Societal-Level Predictors of Groups' Drinking Patterns: A Research Synthesis from the Collaborative Alcohol-Related Longitudinal Project

Kaye Middleton Fillmore, PhD, Jacqueline M. Golding, PhD, E. Victor Leino, PhD, Catherine R. Ager, BA, and Heidi P. Ferrer, BS, with the Collaborative Alcohol-Related Longitudinal Project

ABSTRACT

Objectives. Period effects of per capita consumption of alcohol and divorce rates are assessed for change in quantity and frequency among age/sex groups in multiple longitudinal studies.

Methods. Twenty-five studies of quantity and 29 studies of frequency are used. Studies are from 15 nations and cover periods of 1 to 21 years. Models predict the standardized mean difference for quantity and frequency based on period effects and group-level and methodological variables.

Results. When both the period effects of per capita consumption and the divorce rate are considered, the divorce rate significantly predicts change in quantity and frequency. An increase in the divorce rate is associated with a stronger decrease in frequency among younger people; men are more likely than women to decrease their frequency of drinking when divorce rates rise.

Conclusions. Multiple societal-level factors should be considered critical in influencing the drinking patterns of groups. These results suggest that an increase in the divorce rate is associated with more "dry" social contexts, characterized possibly by drinking patterns of a more "volitive" nature (i.e., heavier quantity per occasion and less frequent drinking). (*Am J Public Health.* 1994; 84:247–253)

Introduction

Understanding social factors that contribute to change in drinking practices within groups is a challenging research task. Traditionally, several designs have been used to address this issue, including historical analyses,[1] aggregate-level statistics,[2,3] and cross-sectional general population studies.[4,5]

This paper uses an alternative design to address alcohol-related social change in groups. It systematically combines results from multiple longitudinal studies of the general population and evaluates the associations of both societal and study-level characteristics with the dependent variables: the mean differences of quantity per occasion and the frequency of drinking between final measurement (T_2) and Time 1 (T_1) for age/sex groups. Societal-level statistics are the primary independent variables of theoretical interest in predicting group-level change of drinking practices.

The advantages of the cross-level design are that (1) multiple samples are used, representing different historical periods and national contexts; (2) characteristics of groups *within* their own societies/period are used as predictors in addition to societal-level predictors; (3) period effects (i.e., historical influences on the lives of individuals measured as change over the study period) in multiple social settings are systematically evaluated using societal-level factors; and (4) effects may be evaluated over variable lengths of time using samples of differing measurement intervals.

Two societal-level explanations are advanced to explain changes in group drinking:

1. The dominant theory maintains that the proportion of drinkers at high levels of intake (e.g., 40 to 80 or more g/day) is related to the average consumption level in a group (typically measured by the overall per capita consumption of alcohol in nations).[2,6,7] Our analysis addresses the association between changes in the per capita consumption of nations and shifts in the means of drinking measures among specific age/sex groups in those nations. Thus, we can determine if shifts in per capita consumption affect all groups in the society equally. To do this, we ask two questions. First, controlling for characteristics of the age/sex groups and the samples, do the Time 1 per capita consumption and the change over time (the period effect) of per capita consumption predict the mean differences in quantity per occasion and frequency per month for various age/sex groups? We expect the period effect of increasing per capita consumption to be associated with increases in the frequency and decreases in the quantity of drinking per occasion because "wet" societies have been characterized by higher frequency of drinking and more moderate quantity per occasion.[8] Second, are some age groups (and gender) more likely to be affected by the period effect than others?

2. Divorce has been linked to high-intake drinking on at least two levels of analysis: (1) cross-sectional studies of the

general population report that the proportion of drinkers at high levels of intake is negatively associated with the stability of marriage on the individual level[9]; and (2) divorce rates, with other indicators of societal-level stress, have been linked to higher per capita consumption and alcohol problems.[10] Using divorce rate as a measure of societal-level stress, we again ask two questions. First, controlling for characteristics of the age/sex groups and the samples, do the Time 1 divorce rate and change in the divorce rate between measurements (the period effect) predict the mean differences in quantity and frequency for age/sex groups? Second, are some age groups (and gender) more likely to be affected by the period effect than others?

3. The final model tests the joint contribution of the Time 1 measures and the period effects of divorce and per capita consumption in predicting the mean changes in quantity and frequency.

The paper is based on the idea that societal-level changes (i.e., period effects measuring the variable at two points in time, T_2–T_1) may be implicated in changing the drinking patterns of groups in multiple societies/periods. It addresses the possibility that the period effects may be differentially distributed within the societies/periods by the age and sex of the groups studied. Finally, it tests the independent effect of each of the societal-level/period variables by controlling for the other.

Methods

Twenty-five studies from the archive of the Collaborative Alcohol-Related Longitudinal Project[11] were used to measure the quantity of drinking per typical occasion; 29 studies were used to measure the frequency of drinking per month. These studies represent sample sizes ranging from 535 to 12 686. Samples consist of abstainers and drinkers at Time 1. Studies are from Canada, Czechoslovakia, Denmark, the Federal Republic of Germany, Finland, Ireland, Israel, New Zealand, Norway, Poland, the Shetland Islands, Sweden, Switzerland, the United Kingdom, and the United States; periods of measurement range from 1960 to 1986 at Time 1. Intervals between measurements range from 1 to 21 years. After studies were disaggregated by age of first measurement in 5-year increments between ages 9 and 39, and in 10-year increments to 80 years and older, effect estimates from samples were calculated for designated age/sex categories yielding a base (n) of 141 for the frequency analysis and of 134 for the quantity analysis.

Basically, the models tested herein are ones in which changes in drinking between two points in time among designated age/sex groups from the different studies are the objects of inquiry. These changes are the effect sizes. The primary variables thought to predict these changes are the period effects of per capita consumption of alcohol and divorce rates over the same period in which the changes in drinking were observed in the various studies. Other variables thought to contribute to these changes are the age and gender of the groups and the characteristics of the study in which the change was measured. These measures and the model are detailed below.

The dependent variables are the standardized mean differences of frequency of alcohol consumption and of quantity per occasion between final measurement and Time 1, both recoded to consistent levels of measurement across the studies to reflect current drinking in the last month.

Demographic variables hypothesized to influence the distribution of effect estimates are the age of the group at Time 1 and the sex of the group (0 = female; 1 = male). Study characteristics are the interval in years between measurements and the percentage of attrition in the sample between Time 1 and final measurement.

Societal-level variables are (1) per capita consumption of alcohol in the nation at Time 1 in US gallons of absolute alcohol (T_1PCC), (2) the difference in per capita consumption between final measurement and Time 1 (D-PCC), (3) the interaction of age of the group at Time 1 and per capita consumption at Time 1 (T_1Age × T_1PCC), (4) the interaction of gender of the group and per capita consumption at Time 1 (Sex × T_1PCC), (5) the interaction of age at Time 1 and the difference in per capita consumption between final measurement and Time 1 (T_1Age × D-PCC), (6) the interaction of gender and the difference in per capita consumption between final measurement and Time 1 (Sex × D-PCC), (7) the Time 1 divorce rate per 1000 (T_1Div), (8) the difference in the divorce rate between final measurement and Time 1 (D-Div), (9) the interaction of age at Time 1 and the Time 1 divorce rate (T_1Age × T_1Div), (10) the interaction of gender and the Time 1 divorce rate (Sex × T_1Div), (11) the interaction of age at Time 1 and the difference in the divorce rate between final measurement and Time 1 (T_1Age × D-Div), and (12) the interaction of gender and the difference in the divorce rate between final measurement and Time 1 (Sex × D-Div). The natural logs were taken of T_1PCC and T_2PCC, and the difference was formed (D-PCC). The interaction terms are included to test the hypotheses that the associations of the societal variables at Time 1 or their period effects with changes in quantity or frequency differ for age groups and gender.

The unit of analysis used for comparison across studies is the effect size, or the standardized difference between mean frequency of alcohol consumption at first and final measurement points.[12] The standardized mean difference indicates the degree to which (and the direction in which) age/sex groups are, relatively speaking, stable or changing. The effect size has been widely used in meta-analyses because of its ready interpretability as a scale-free estimate of the magnitude and direction of effects. Originally developed to compare results from treatment and control groups in experimental studies, the measure can also be used effectively in nonexperimental longitudinal research. For this purpose, the effect size constitutes a scale-invariant estimate of the magnitude and direction of group change over time, expressed in standard deviation units. All values reported here have been calculated using the variant formulation of the effect size developed by Hedges and Olkin[13] because of its superior properties as an estimate of the population effect size in small sample contexts.

Estimates of the relative impact of multiple factors on effect sizes are generated by using weighted least squares regression procedures with effect sizes as the dependent variable. Each study result is weighted by the reciprocal of the variance of the effect size, thus giving greater weight to more precise estimates.[13] Results of each model include a standardized regression coefficient (β) for each predictor and a test of the significance of its relationship to the dependent variable. The use of the standardized regression coefficient (the effect on the dependent variable, in standard deviation units, of a one–standard deviation change in an explanatory variable) should be distinguished from the use of the standardized mean differences (the effect sizes), which are the "standardized" dependent variable values. The null hypothesis for this analysis is that there is no influence of the societal independent variables on the stan-

dardized mean differences after adjusting for demographic factors and study characteristics.[12]

The correlations between the primary societal-level factors for the quantity and frequency samples (Table 1) indicate that rising per capita consumption occurs in studies where T_1PCC was originally relatively low; the correlation between T_1Div and D-Div is much more modest; and T_1Div and T_1PCC are virtually unrelated. D-Div and D-PCC are positively related, suggesting that increases in these period effects sometimes co-occur in the samples studied.

TABLE 1—Correlations between the Primary Societal-Level Variables for the Frequency of Drinking Sample and the Quantity of Drinking Sample

Note. T_1PCC = Time 1 per capita consumption of alcohol; T_1Age × T_1PCC = the interaction of age at Time 1 and per capita consumption of alcohol at Time 1; Sex × T_1PCC = the interaction of gender and Time 1 per capita consumption of alcohol.

Results

Per Capita Consumption of Alcohol

Table 2 displays the cross-sectional relationships of frequency/quantity at Time 1 with age of the group, sex of the group, T_1PCC, and T_1Age × T_1PCC in the first two models. Sex × T_1PCC is substituted for T_1Age × T_1PCC in the second two models.

Age is not significantly associated with quantity and is positively associated with frequency, suggesting that older groups drink more often. Men show higher frequency and quantity in the aggregate than women do.

T_1PCC is not significantly associated with quantity or frequency although the associations are approaching significance and are positive. The interaction of T_1Age × T_1PCC is not associated with frequency in a statistically significant way but is negatively associated with quantity. Models calculated for separate age groups show that young people in higher per capita consumption contexts are more likely to drink more heavily on each occasion than are young people in lower per capita consumption contexts, and quantity per occasion among those in their middle and later years is not related to per capita consumption context. The interaction of Sex × T_1PCC is not significantly related statistically to either frequency or quantity.

To assess the associations of the period effects of D-PCC with the mean change of quantity and frequency and to examine which age/sex groups, if any, are affected, the effects of age, sex, interval between measurements of the studies, sample attrition, T_1PCC, the period effects of D-PCC, and T_1Age × D-PCC are simultaneously entered in the first two models (Table 3); Sex × D-PCC is substituted for T_1Age × D-PCC in the second two models.

Age is not significantly related to the mean difference of quantity but is negatively related to that of frequency. There are no significant gender differences. The interval between measurements of studies is positively related to frequency and negatively related to quantity, indicating that groups with longer intervals between measurement will show greater increases in frequency and greater decreases in quantity. Sample attrition is not significantly related to quantity but is positively related to frequency, indicating that groups with higher attrition increase in mean frequency over time.

There are no main effects of T_1PCC on the mean change of quantity or frequency. There is no main effect of D-PCC on the mean difference of frequency but there is a positive (albeit marginal) effect on the mean difference of quantity, suggesting that quantity per occasion rises with the period effect of D-PCC. (Noteworthy, however, is that the correlation of D-PCC and the mean difference of quantity is close to zero.) The relationships of the interactions of T_1Age × D-PCC and Sex × D-PCC with the mean difference of either quantity or frequency are not significant.

The Divorce Rate

Table 4 displays the cross-sectional relationships of frequency/quantity at Time 1 with age of the group, sex of the group, T_1Div, and T_1Age × T_1Div in the first two models. Sex × T_1Div is substituted for T_1Age × T_1Div in the second two models.

T_1Div is positively associated with T_1 frequency and T_1 quantity (the latter being only marginally significant), suggesting that higher societal-level stress is associated with both heavier and more frequent drinking in the cross-section. The interac-

	Multiple R = .652; F = 25.187; P = .000; df = 136			Multiple R = .343; F = 4.312; P = .003; df = 129		
Age	.420	.065	.000	−.044	.084	.595
Sex	.441	.065	.000	.315	.083	.000
T_1Div	.266	.067	.000	.167	.085	.053
Sex × T_1Div	.083	.066	.211	−.025	.084	.770
	Multiple R = .657; F = 25.833; P = .000; df = 136			Multiple R = .343; F = 4.309; P = .003; df = 129		

Note. T_1Div = Time 1 divorce rate; T_1Age × T_1Div = the interaction of age at Time 1 and the Time 1 divorce rate; Sex × T_1Div = the interaction of gender and the Time 1 per capita consumption of alcohol.

tions of either age or gender with T_1Div are not significant.

Assessment of the period effect (Table 5) simultaneously enters the effects of age, sex, interval between measurements of the studies, sample attrition, T_1Div, D-Div, and the interaction of T_1Age × D-Div in the first two models; the interaction of Sex × D-Div is substituted for T_1Age × D-Div in the second two models.

T_1Div is negatively related to the mean difference of quantity (marginal) and frequency, suggesting that groups originally in "high" divorce rate contexts will decrease and groups in "low" divorce rate contexts will increase their quantity and frequency over time. D-Div is positively associated with the mean difference of quantity and negatively associated with the mean difference of frequency, suggesting that when divorce rates rise, quantity per occasion will rise and frequency will fall.

T_1Age × D-Div is not statistically significant for the mean difference of quantity but is marginally significant for frequency, indicating that frequency is likely to fall among all age groups with a rising divorce rate but that the association is stronger among the young. (Separate models for age groups [not shown] demonstrate this finding.) The interaction of gender and the period effect of the divorce rate is not associated with quantity but is negatively associated with frequency. Separate models for each sex (not shown) reveal that while both men and women show decreases in frequency when the divorce rate increases, the effect is stronger and significant among men and is not significant among women.

The Independent Societal-Level Period Effects of per Capita Consumption and the Divorce Rate

To determine if the period effects of either per capita consumption or the divorce rate are associated with the mean differences after controlling for the other period effect, age, sex, interval between measurements of the studies, sample attrition, T_1Div, T_1PCC, D-PCC, and D-Div are simultaneously entered (Table 6).

The period effect of per capita consumption is not significantly associated with the mean difference of quantity when the period effect of the divorce rate is in the model; however, it is marginally significant (positive) in association with the frequency of drinking per month. Noteworthy is that the sign changes: a positive correlation and a negative beta. This is therefore interpreted with caution owing to the multicolinearity among the independent variables and to the low correlation between D-PCC and the mean frequency of drinking.

The period effect of the divorce rate is negatively associated with the mean difference of frequency and positively associated with the mean difference of quantity.

Thus it can be concluded that when both societal-level effects are entered into the same model, an increase in the per capita consumption of alcohol may be implicated in changing the mean frequency

of drinking. However, the divorce rate is more likely to have a significant influence over time, indicating an elevation of the quantity of drinking and a decrease in the frequency.

Discussion

This paper assesses the period effects of per capita consumption of alcohol and divorce rates on change in quantity of drinking per occasion and on frequency of drinking per month among age/sex groups drawn from multiple longitudinal studies representing different historical periods and nations. The basic assumption in the analysis is that alcohol-related social change within groups is not random but, instead, is at least partly derived from larger societal changes.

Noteworthy is that these analyses are concerned with the mean difference of quantity per occasion and frequency per month of age/sex groups, not with the proportions of persons in these populations who are heavy and/or frequent drinkers. This being the case, large mean changes would not necessarily suggest that it is the more entrenched heavy and/or frequent drinkers who are changing but, rather, that it is larger portions of the population.

Clearly the strongest effect in the period effect models is the interval of time between measurement points (ranging from 1 to 21 years), characterizing this group of studies as increasing in frequency and decreasing in quantity as interval of time increased.

Some results both reflect and inform understanding of maturation with respect to drinking. Previous cross-sectional research has shown that age is positively related to frequency of drinking and negatively related to quantity per occasion.[14] While only approaching significance, the cross-sectional results of the interaction between age and per capita consumption at Time 1 suggest that younger people in higher per capita consumption contexts are more likely to drink more per occasion than younger people in lower per capita consumption contexts, whereas older people in both contexts are not differentiated by their quantity per occasion. This interpretation is stated with caution.

The longitudinal findings also refine what we know about maturation and drinking. While the interaction of age and the period effect of the divorce rate is only marginally significant, it suggests that the frequency of drinking falls among all age groups when divorce rates increase but that the relationship is stronger among the young. The lesser effect among older groups may be owing, in part, to the collective influence of the increased prevalence of divorced persons in these groups, which, along with the group's changing drinking patterns, our past research has shown to be related to changing individual-level drinking patterns.[15,16] While this suggests that an increase in societal-level stress might be implicated in altering the decline in frequency observed as a result of increasing age among the cohorts most likely affected, it should be remembered that the nations under scrutiny vary with respect to the socioreligious constraints on divorce (e.g., annulment and separation in some countries may be equivalent to divorce in others). But even taking this caveat into consideration, if social stress (in this case, divorce rates) increases, such a contextual effect could change the trajectory in age cohorts from what would be

expected from maturation alone. Such an effect could reflect increased group cohesiveness among older persons; alternatively, it could also reflect sample attrition among this age group. However, if the change in divorce rate changes the "natural" trajectory of the frequency of drinking as people mature, special attention to this age group may be warranted.

Therefore, these two social forces, one measuring the normative relative "wetness" of a society and the other measuring an aspect of social stress, may interact with age in ways that give us insight beyond the effects of maturation alone.

One interaction of gender with the societal-level measures is significant for the period effect findings. The interaction between the period effect of the divorce rate and gender in association with the mean difference of frequency indicates that frequency significantly decreases among men but not among women in contexts of increasing divorce rates. It is shown that the main effect of an increasing divorce rate is associated with decreasing frequency and increasing quantity of consumption. This may mean that societal stress is related to the emergence of a "drier" society as evidenced by the decreased frequency of drinking among the young, particularly among men, and by the increased quantity per occasion among all groups.

The cross-sectional findings widen our understanding of the relationships of both per capita consumption of alcohol and the divorce rate to drinking. As expected, Time 1 per capita consumption is positively related to Time 1 frequency of drinking (marginal), and Time 1 divorce rate is positively related to both Time 1 frequency and quantity (marginal for quantity). This suggests that both norms of the relative wetness of societies and indicators of social stress may be useful in describing the drinking of the groups in those societies and periods studied. However, knowledge of the per capita consumption at Time 1 is of less importance in predicting the mean difference of frequency and quantity. On the other hand, the divorce rate is a relatively strong predictor of the mean difference of both quantity and frequency (in models where only divorce rates are evaluated) and of frequency only (in models including the per capita consumption measures), such that groups originally in higher Time 1 divorce rate contexts are more likely to decrease in frequency over time. The latter finding may also suggest a regression to the mean as well as the "law of initial value" (i.e., the greater the distance from the mean, the greater the change possible). Alternatively, it may suggest that societies characterized by higher social stress are more likely to be heavier and more frequent drinkers initially but, as these groups age, both heavy and frequent drinking are likely to decrease, most probably owing to maturation (a finding that has been observed in most studies and at most ages in the middle to later years of life).[14]

Finally, the impact of the period effects themselves requires comment. The period effects of changing per capita consumption on group drinking practices are not as strong as expected when using this research design. (The effect is positive on quantity for models without the divorce rate variables included and nonsignificant when those variables are included, and the effect is negative on frequency for models with the divorce rate variables included and nonsignificant when those variables are not included.) While a change in per capita consumption would be expected to mold the *volume* of drinking in these groups (both being equivalent under the ideal conditions of measurement), the mean differences do not respond consistently across models to these period effects. This calls for caution in developing societywide programs to curtail per capita consumption because it may not be as strong a variable in molding the drinking *patterns* of groups as previously thought.

When the two period effects are entered, it is the divorce rate that shows a significant negative association with the mean difference of the frequency of drinking and a positive association with the quantity of drinking, suggesting that this form of societal-level stress may alter drinking patterns by possibly transforming the groups' social contexts into "drier" ones. This suggests, but certainly does not prove, that societal-level stress may be related to the emergence of more "volitive" drinking patterns, a hypothesis worthy of future pursuit.

These findings suggest that there is merit in consideration of multiple societal-level factors as period effects in the study of social change surrounding drinking. The practical importance is that some specialists in alcohol-related prevention have suggested that intervention on the societal level, such as reducing the per capita consumption of alcohol, will reduce the average consumption in a group and hence reduce the proportion of heavy drinkers in the society. But while this may be true of the overall volume of drinking, it does not seem to be consistently the case in drinking patterns of age/sex groups. Results here suggest that a reduction in the incidence of divorce in society may be associated with a wetter social context by curbing an increase in quantity per occasion and stimulating an increase in frequency. However, if the problems of a dry social context are to be avoided, reduction in this form of societal-level stress may not be warranted. Nonetheless, it seems probable that a reduction in the divorce rate might reduce more volitive drinking (although that remains to be demonstrated) and may perhaps have more beneficial effects for a larger group of social problems. □

Television Beer Advertising and Drinking Knowledge, Beliefs, and Intentions among Schoolchildren

Joel W. Grube, PhD, and Lawrence Wallack, DrPH

ABSTRACT

Objectives. The relationships between television beer advertising and drinking knowledge, beliefs, and intentions were investigated in a survey of schoolchildren. The research was guided by a theoretical model specifying that awareness of advertising, and not mere exposure, is necessary for it to have an effect on beliefs or behaviors.

Methods. Participants were a random sample of 468 fifth- and sixth-grade schoolchildren from a northern California community. Data were collected in the home with a combination of self-administered questionnaires and structured interviews.

Results. Nonrecursive statistical modeling indicated that awareness of television beer advertising was related to more favorable beliefs about drinking, to greater knowledge of beer brands and slogans, and to increased intentions to drink as an adult. The effects of advertising awareness on knowledge, beliefs, and intentions were maintained when the reciprocal effects of beliefs, knowledge, and intentions on awareness were controlled.

Conclusions. The findings suggest that alcohol advertising may predispose young people to drinking. As a result, efforts to prevent drinking and drinking problems among young people should give attention to countering the potential effects of alcohol advertising. (*Am J Public Health.* 1994;84:254–259)

Introduction

Children have well-developed beliefs about alcohol and its effects even before they have personal experience with drinking.[1–4] Although parents, peers, and other environmental influences are important in shaping these beliefs and, ultimately, drinking behaviors, alcohol advertising also may be an important source through which children learn about this drug. Popular belief in the effects of alcohol advertising is widespread. A recent survey conducted by an alcohol industry group found that 73% of the general public agreed that alcohol advertising is a major contributor to underage drinking.[5] Similarly, two recent federal reports have recommended that alcohol advertising, especially that directed at young people, be limited or banned and that equal time requirements be established to provide for the dissemination of public health messages about drinking.[6,7] In addition, legislative proposals in the US Senate and House of Representatives would require health messages on alcoholic beverage advertisements in the print and electronic media. To what extent are concerns about the influence of alcohol advertising on young people well founded? The present study addressed this issue by investigating the relationships between awareness of television beer advertising and drinking knowledge, beliefs, and intentions of schoolchildren.

Most of the available research on alcohol advertising and youth has shown small but significant correlations between exposure to alcohol advertising and drinking beliefs and behaviors. In one study, exposure to alcohol advertising was found to be related to heavy drinking, problem drinking, and drinking in hazardous situations (e.g., while driving) among youth.[8] These relationships persisted when demographic variables and beliefs about drinking by peers and parents were statistically controlled. Another study showed that adolescents who were heavily exposed to advertising were more likely to agree that drinkers possess valued characteristics such as being attractive, athletic, or successful.[9] More recent research has shown that young drinkers are more likely to be exposed to alcohol advertisements, are more accurate in identifying brands of beer from edited alcohol advertisements, and are more favorably disposed toward these advertisements than are nondrinkers.[10] A few studies have found that exposure to advertising is only modestly related to consumption of alcohol by young people when significant demographic and personal variables are controlled.[11,12]

Although most studies have found a significant relationship between alcohol advertising and drinking beliefs and behaviors among young people, some issues remain. At a conceptual level, most researchers have assumed that simple exposure to alcohol advertising is sufficient to bring about attitude and behavioral changes. However, an information processing model of advertising suggests that advertisements have significant effects on knowledge, beliefs, intentions, and behaviors only when attended to and remembered.[13,14] According to this perspective, *awareness* of advertising, not simply ex-

posure to it, is important. By focusing on simple exposure, previous studies may have underestimated the importance of advertising for the drinking beliefs and behaviors of young people. In addition, previous research has relied on correlational analyses. As a result, it provides no evidence regarding the direction of the relationship between alcohol advertising and drinking beliefs and behaviors.[15] Although alcohol advertising may influence these beliefs and behaviors, it is also possible that those who are predisposed to drink seek out information about alcohol and thus are more attentive to relevant advertising.

The present study attempted to address some of these issues through an investigation of television beer advertising and drinking knowledge, beliefs, and intentions among schoolchildren. Going beyond earlier studies, an information processing model of advertising effects was used to guide the design and analyses. In addition, nonrecursive statistical modeling techniques were used to estimate the effects of awareness of television beer advertising on drinking knowledge, beliefs, and intentions and the simultaneous effects of knowledge, beliefs, and intentions on awareness.

Methods

Procedures

Overview. Data were obtained from a sample of schoolchildren in a suburban city in northern California. The data were collected in the home by trained interviewers from the Survey Research Center of the University of California, Berkeley. Sensitive questions, such as those addressing drinking intentions, were included in a self-administered instrument. Less threatening questions such as those about television viewing were included in a face-to-face interview. One of the child's parents completed a self-administered questionnaire and answered several interview questions concerning family background and demographics. Approximately 1 hour was required to complete the interviews and surveys. A $10 compensation was offered to reimburse the parents and child for their time.

Sample. The initial sample consisted of 603 fifth and sixth graders drawn at random from a complete roster provided by the local public school district. Interviews were completed with 468 children (a response rate of 77.6%).

The final sample was nearly evenly split between boys (48.9%) and girls (51.1%). The respondents ranged in age from 10 to just under 14 years old. Their median age was 11.9 years. About 32% of the children were Caucasian, 29% were Asian American (predominantly Filipino, but also including Chinese, Japanese, and Southeast Asian), 26% were African American, 7% were Latino, 4% were Pacific Islander, and 3% were of other ethnic or racial heritages. The sample was largely working and middle class, and the median family income was $33 000. Most parents reported some education beyond high school, and mothers and fathers had both completed an average of about 13 years of education.

Measures

Television viewing. Weekday television viewing was determined by asking the children how much time they spent watching television on a typical school day before school, after school until dinner, and from dinner until bedtime. Also, four weekend viewing periods were addressed: Saturday morning until noon, Saturday noon until bedtime, Sunday morning until noon, and Sunday noon until bedtime. These items were summed into separate measures representing hours of weekday viewing, hours of weekend morning viewing, and hours of weekend afternoon and evening viewing. The children also were asked how many televised sports events they had viewed in the last 4 weeks ("none" to "three or more"). This question was included because television sports have very high rates of alcohol advertising.[16]

Awareness of beer advertising. Awareness of beer advertising was measured during the interview by showing the children five still photographs from currently televised beer commercials (Coors Light, Budweiser Light, Coors, Michelob Dry, Budweiser). Any references to product or brand were blocked out of the photographs. The children were asked whether they could remember having seen the commercial depicted in each photograph and, if so, to name the brand being advertised. These items were scored 0 (had not seen the advertisement), 1 (had seen the advertisement but could not name the brand), or 2 (had seen the advertisement and named the correct brand).

Knowledge of beer brands and slogans. Knowledge of beer brands was measured by asking the children to name as many brands of beer as they could without any prompts. The interviewer recorded up to five different brands. Next, the interviewer presented the children with a list of five beer slogans. The children were asked to match each slogan with its correct brand. A summary measure was derived by counting the number of correct matches.

Alcohol beliefs. Beliefs about the positive aspects of drinking were measured by reading the children five statements that addressed alcohol's relation to (1) friendship or sociability, (2) reward for work, and (3) relaxation. These items were chosen to reflect the main themes in beer advertisements as identified in previous research.[17] The children were asked to indicate, on 4-point scales, the extent to which they thought each item was true or false ("certain it is true" to "certain it is false"). Negative beliefs were similarly measured with five items targeting (1) birth defects, (2) drinking and driving, and (3) general health problems.

Intention to drink as an adult. Because drinking levels are very low for this age group, the primary outcome variable was intention to drink as an adult. (Because only 5% of the respondents had ever had more than a taste of an alcoholic beverage, it was not possible to investigate the effects of advertising on drinking. However, drinking intentions have been found to be related to future drinking behaviors among adolescents.) Intentions were ascertained on the self-administered questionnaire with items asking the children to indicate, on 4-point scales, how often they thought they would drink beer, wine coolers, wine, and liquor when they were grown up ("at least once a week" to "not at all").

Perceived parental and peer approval of drinking. Measures of perceived approval were obtained on the self-administered questionnaire by asking the children to indicate, on 5-point scales, how happy or unhappy their mothers, fathers, best friends, and other close friends would be if the children themselves were to drink alcohol. Scales representing parental approval ($\alpha = .84$) and peer approval ($\alpha = .79$) were derived by calculating the mean values of the relevant items.

Perceived parental and peer drinking. Perceptions of parental and peer drinking were measured in the self-administered questionnaire by having the children indicate, on 6-point scales, how often they thought their mothers, fathers, best friends, and other friends had consumed alcohol in the past year ("none" to "almost every day"). Mean scores for parental drinking ($\alpha = .62$) and peer drinking ($\alpha = .81$) were calculated.

TABLE 1—Measurement Models for Latent Variables

Measured Variable	Standardized Factor Loading	Unstandardized Factor Loading	SE	t	P
Drinking intention					
Liquor	.58	1.00	...	...	...
Beer	.81	2.37	.272	8.68	<.001
Wine coolers	.71	1.91	.235	8.11	<.001
Wine	.58	1.59	.210	7.59	<.001
Positive beliefs					
Bars are a good place to hang out	.48	1.00	...	...	...
Having a few beers is a good reward	.72	1.29	.162	7.97	<.001
Drinking makes it easier to get to know people	.57	0.92	.133	6.91	<.001
Drinking is a good way to relax	.69	1.10	.137	8.03	<.001
Good friends drink together	.64	1.22	.157	7.79	<.001
Negative beliefs					
Drinking can harm health	.53	1.00	...	...	...
Dangerous to drive after drinking	.75	1.59	.254	6.23	<.001
Mother's drinking can harm unborn child	.45	0.84	.166	5.06	<.001
Mother's drinking can cause birth defects	.39	0.84	.171	4.92	<.001
Shouldn't ride with drinking driver	.52	1.20	.214	5.59	<.001
Awareness of advertising					
Coors Light	.47	1.00	...	...	...
Budweiser Light	.40	0.95	.158	5.98	<.001
Coors	.36	0.83	.149	5.57	<.001
Michelob Dry	.34	0.77	.145	5.35	<.001
Budweiser	.33	0.92	.169	5.44	<.001

Note. The unstandardized loading of the first variable on each factor was fixed at 1 to identify the variance of the latent variables.

Demographic and background variables. Family income and child's ethnicity were obtained from the parent's self-administered questionnaire, age was asked directly of the child, and sex was recorded by the interviewer. Ethnicity was coded into four dummy variables representing Caucasian, Black, Asian, and Latino respondents. Sex was also coded as a dummy variable (0 = female, 1 = male).

Results

The relationships between awareness of advertising and drinking intentions, beliefs, and knowledge were examined through a generalized least squares, nonrecursive structural equations analysis implemented with EQS.[18,19] Because the data were nonnormal, robust estimates of the standard errors were obtained and the Satorra-Bentler scaled chi-square was used to assess the fit of the models.[20]

Latent variables were used to represent awareness of beer advertising, drinking intentions, beliefs about the positive aspects of drinking, and beliefs about the negative aspects of drinking. Table 1 provides the factor loadings from the measurement model for these latent variables. Correlations were allowed between error terms for four pairs of items in the measurement model: (1) wine and wine cooler intentions ($r = .22$, $P < .001$), (2) liquor and wine intentions ($r = .22$, $P < .001$), (3) beliefs that drinking can harm an unborn child and that drinking can cause birth defects ($r = .24$, $P < .001$), and (4) recognition of the Budweiser Light commercial and belief that drinking is a good reward after a day's work ($r = .18$, $P < .001$). (In order to ensure empirical identification of the model, an equality constraint was placed on the correlations between the errors for wine and wine cooler intentions and the errors for wine and liquor intentions. The Lagrange multiplier test indicated that this constraint was reasonable, ($\chi^2[1, n = 458] = 0.11$, $P < .75$.)

The information processing framework was translated into an initial structural model specifying unidirectional effects from awareness of beer advertising to beliefs and knowledge and from beliefs to intentions. Exogenous variables considered to be important as potential predictors of awareness, knowledge, beliefs, and intentions were included in the covariance matrix for the initial model, but no effects between these variables and the endogenous variables were specified. (The exogenous variables included in the initial model were frequency of viewing sports programs, hours of weekend morning television viewing, hours of weekend afternoon and evening television viewing, hours of weekday television viewing, perceived parental approval of drinking, perceived peer approval of drinking, perceived parental drinking, perceived peer drinking, race, age, sex, family income, and years of parents' education.) After the initial model was solved, a specification search was undertaken with Lagrange multiplier tests to ascertain which exogenous variables were related to endogenous variables. Effects were added to the model only if they also were consistent with previous research and theory.[21] Exogenous variables that were unrelated to any of the endogenous variables were dropped. Next, the paths representing the reciprocal effects of positive beliefs and knowledge on awareness of advertising and of intentions on positive beliefs were added, and the model was reestimated. (One way to uniquely identify these simultaneous effects is to specify exogenous variables that have independent direct effects on each of the endogenous variables involved in a reciprocal relationship. Because no exogenous variable uniquely predicted negative beliefs, the reciprocal paths involving this variable were not estimated.) These reciprocal effects were retained in the model even when they were nonsignificant in order to control for the potential influences of knowledge, beliefs, and intentions on awareness. Finally, correlations between the disturbance terms for knowledge of brands and positive beliefs ($r = .30$, $P < .01$) and knowledge of slogans and positive beliefs ($r = .22$, $P < .01$) were added to the model. The final structural model is depicted in Figure 1 (solid arrows represent statistically significant effects, and broken arrows represent nonsignificant effects). This model provided a good fit, scaled χ^2 (330, n = 458) = 369.88, $P < .07$. The normed and comparative fit indexes for this model were .976 and .997, respectively.

Table 2 shows the structural (regression) coefficients and significance tests from the final model. Four findings are particularly noteworthy. First, awareness of alcohol advertising was significantly re-

lated to increased knowledge of beer brands and slogans and to more positive beliefs about drinking. Second, awareness was *indirectly* related to intentions to drink as an adult through positive beliefs ($\beta = .19$, $t = 2.11$, $P < .05$). Third, awareness of advertising was not significantly related to beliefs about the negative aspects of drinking. Fourth, knowledge of beer brands and slogans increased awareness of advertising.

In addition, children who expected to drink more frequently as adults had more favorable beliefs about drinking, believed that their peers were more approving of drinking, and believed that their parents drank more frequently. They also tended to be male and had parents with more years of education. Sex also had an independent effect on intention to drink beer over and above its effect on overall drinking intention. Boys reported that they were more likely than girls to drink this beverage as an adult ($\beta = .10$, $t = 2.51$, $P < .05$).

Children who perceived more parental approval of drinking believed that drinking was more likely to have positive consequences. Also, children who perceived more peer approval of drinking thought drinking was less likely to have negative consequences. Similarly, children who believed that their peers drank more frequently knew more beer slogans, and children who perceived more peer approval for drinking named more brands of beer. Boys also knew more slogans and brands than did girls. Finally, children who were more aware of alcohol advertising also believed that their parents drank more frequently and were more frequent viewers of sports and weekend afternoon and evening television.

Discussion

Children who were more aware of beer advertisements held more favorable beliefs about drinking, intended to drink more frequently as adults, and had more knowledge of beer brands and slogans. These effects were maintained when the reciprocal effects of knowledge, beliefs, and intentions on awareness were included in the model. Thus, the findings provide support for the hypothesis that awareness of alcohol advertising *influences* children's drinking beliefs, knowledge, and intentions. Interestingly, awareness of advertising was unrelated to beliefs about the negative aspects of drinking. This finding may reflect the fact that alcohol advertisements overwhelmingly associate drinking with positively valued activities and consequences such as romance, sociability, and relaxation.[17]

Significant reciprocal effects were also found. Knowledge of beer brands and slogans appeared to increase awareness of

beer advertising. These reciprocal effects may result from the fact that children who are curious about drinking seek information about alcohol. Beer commercials may represent one source of such information.

Although the present study goes beyond previous research on alcohol advertising and youth, there are two issues that should be kept in mind in evaluating the results. First, it was not possible to address drinking behaviors. Because only 5% of the children had ever had a whole drink, it was inappropriate to include this variable in the analysis. Similar research with older adolescents will be necessary to investigate the relationship between alcohol advertising awareness and drinking behaviors. Second, the findings are based on cross-sectional data. Although, when reciprocal effects are controlled, the results still show an association between awareness of alcohol advertising and drinking knowledge, beliefs, and intentions, it is possible that different model specifications might lead to different conclusions about the exact sizes and nature of these effects. Further research should be undertaken to replicate these findings and increase confidence in them. Studies using longitudinal methods would be particularly useful.

Taken as a whole, the findings suggest that attempts to prevent or delay drinking among young people should give attention to alcohol advertising. In particular, efforts should be made to reduce the extent to which it appeals to children and to reduce their exposure to it. A number of strategies are possible to achieve these goals.

Restricting television alcohol advertising during prime viewing hours for children and limiting alcohol sponsorship of concerts and similar events that are attended by underaged youth might be considered. Addressing alcohol advertising in televised sports would be particularly important. Such actions, however, are controversial and are certain to meet considerable resistance from alcohol advertisers. Another possible approach, assuming that alcohol advertisers do not intentionally set out to influence children and adolescents, is to work cooperatively with these advertisers to reduce the extent to which alcohol advertising appeals to young people. For example, researchers could provide empirical feedback concerning the types of advertisements that are particularly appealing to youth and offer suggestions for improvements. Similar efforts with television producers and writers appear to have reduced inappropriate portrayals of drinking in prime-time fictional programs.[22]

Counteradvertising, such as that used in the California antismoking campaign,[23] also represents a reasonable strategy. However, for counteradvertising to be effective, it must compete with commercial alcohol advertisements in terms of quality, interest, and frequency of exposure. Equal time requirements or the dedication of alcohol tax funds for the production and airing of health messages may be necessary to achieve these goals. Health warning labels in alcohol advertising also may help counteract its overwhelmingly positive messages, although the evidence for the effectiveness of such labeling for children is weak.[24]

Finally, educational efforts are important in helping children develop their critical skills regarding alcohol advertisements. Many school-based prevention programs contain media components teaching young people to recognize persuasive appeals, understand the intent of advertising, and develop counterarguments to those presented in advertisements. The results of such interventions are mixed, although some appear to have had limited success when combined with other educational components.[25,26]

In the final analysis, no single preventive strategy will provide a complete answer. Ultimately, education, public policy, and community activism all will be required to ensure that children understand the role that alcohol and alcohol advertising play in our society. □

Nutritional and Lifestyle Epidemiology Course to Be Held in the Netherlands

The Department of Epidemiology and Public Health and the Department of Human Nutrition, Wageningen Agricultural University, the Netherlands, will be holding an advanced course in nutritional and lifestyle epidemiology May 30 through June 5, 1994. The following methodological issues will be dealt with on an advanced level: study design, exposure assessment, biomarkers, exposure measurement error, data analysis, bias, and effect modification. In addition, lectures will be held on such major issues as antioxidants, non-nutritive food constituents, physical activity, and passive smoking in relation to chronic diseases.

The lecturers will include, among others, Dr D. Hunter, Boston, Mass, Professor L. Kohlmeier, Chapel Hill, NC, Dr B. Margetts, Southampton, UK, Dr P. Piettinen, Helsinki, Finland, and Professor F. J. Kok and Professor W. A. van Staveren, Wageningen, the Netherlands.

Epidemiologist, nutritionists, physicians, health care professionals, and others with a basic knowledge of epidemiology are encouraged to attend.

The cost of the course is 2000 Dutch guilders, which includes hotel accommodation. For more information, contact Esther G. M. Pallast, MSc, Department of Epidemiology and Public Health, Agricultural University Wageningen, P.O. Box 238, 6700 AE Wageningen, The Netherlands; tel +31 8370 84124; fax +31 8370 82782; e-mail Esther.Pallast@medew.hegl.wau.nl.

Emotional and Behavioral Problems and Severe Academic Delays among Sheltered Homeless Children in Los Angeles County

Bonnie T. Zima, MD, MPH, Kenneth B. Wells, MD, MPH, and Howard E. Freeman, PhD

ABSTRACT

Objectives. Few studies have estimated the extent of specific emotional, behavioral, and academic problems among sheltered homeless children. The objectives of this study were to describe such problems, identify those children with the problems, and evaluate the relationship between child problems and use of physical and mental health services.

Methods. From February through May 1991, 169 school-age children and their parents living in 18 emergency homeless family shelters in Los Angeles County were interviewed. To evaluate the answers, interviewers used standardized measures of depression, behavioral problems, receptive vocabulary, and reading.

Results. The vast majority (78%) of homeless children suffered from either depression, a behavioral problem, or severe academic delay. Among children having a problem, only one third of the parents were aware of any problem, and few of those children (15%) had ever received mental health care or special education.

Conclusions. Almost all school-age sheltered homeless children in Los Angeles County have symptoms of depression, a behavioral problem, or academic delay severe enough to merit a clinical evaluation, yet few receive specific care. Programs targeted at sheltered homeless school-age children are needed to close this gap. (*Am J Public Health.* 1994;84:260–264)

Introduction

Families with children are the fastest growing homeless population, making up possibly as much as 40% of the homeless.[1,2] Almost a quarter of the homeless are children and at least 3% are unaccompanied youth.[2] On any given night, it is estimated that 68 000 to 100 000 children have no home and that an additional 186 000 are doubled up in overcrowded conditions.[3] In Los Angeles County alone, the number of homeless children is conservatively estimated to be between 32 000 and 36 000 over a 1-year period.[4]

Living in extreme poverty, homeless children experience substandard living conditions, abrupt residential transitions, and discontinuity in school.[5–7] They are also often raised by a single parent with limited education and inadequate economic and social supports,[8–10] which exacerbates the stress within the family. Earlier studies found that approximately one half of sheltered homeless children in Boston suffer from at least one developmental delay or require psychiatric evaluation for depression or anxiety,[11] and that a majority of children living in Philadelphia's public homeless shelters and New York City's hotels have extremely poor receptive vocabulary and visual motor skills.[9,12,13] Furthermore, many homeless children suffer from untreated acute and chronic physical illnesses[12,14–17] and are without a regular health care practitioner.[14,16,18]

Our study focuses on emotional disorders and severe academic delays among school-age sheltered homeless children living in one of the country's largest metropolitan counties. We targeted school-age sheltered homeless children so we could investigate those children who are most accessible to services through schools and social services while still living with their family, and we included Mexican and Central American families, a population rarely described in the homeless literature. Our objectives were to (1) describe emotional, behavioral, and academic problems among sheltered homeless children; (2) identify characteristics of homeless children with such problems; and (3) relate the use of health services and specific mental health interventions to child need.

Methods

All 22 emergency homeless family shelters that were in operation during the late winter of 1991 were identified from four Los Angeles County homeless service databases. The shelters were placed in random order and surveyed twice between February and May 1991. All families who had stayed at the shelter at least one night and had at least one child between the ages of 6 and 12 years were asked to participate. The parent who knew the child best was interviewed. If there were more than two eligible children in a family, two were randomly selected. One child with severe mental retardation

was excluded. Interviews were conducted in Spanish or English, depending on parent and child preference; the survey instruments were translated and back-translated into Spanish. Academic skills were tested in both languages if the child was bilingual, and the best score was taken.

Measures

Sociodemographic characteristics of the parent and child were obtained from the parent. Child ethnicity was categorized as African American, Latino, non-Hispanic White, or Other. This last category included the few children identified by the parent as being biracial, Asian American, or American Indian.

Homeless history questions were adapted from the RAND Course of Homelessness Study (M. A. Burnam and P. Koegel, personal communication, March 12, 1992). Also obtained were the age the child first became homeless, the amount of time the child spent homeless in the past 12 months, the number of different places in which the child lived in the past 12 months, and the number of different times in this past year the child returned to homelessness after having a home or staying with family or friends for at least 30 continuous days. "Homeless" was defined as having no regular place to live, such as a house, an apartment, a room, or the home of a family member or friend, but instead having to stay in a shelter, an abandoned building, an all-night theater, a car, outdoors, or other such places not meant to be a permanent living space.

Both parental awareness of an emotional or learning problem and child use of health services were assessed using questions from the National Health Interview Survey, 1988 Child Health Supplement.[19] If a parent reported that the child had ever had a delay in growth or development, a learning disability, or an emotional or behavioral problem lasting 3 months or more, the parent was identified as being aware of a problem. When a problem was reported, the parent was asked whether the child had received counseling or treatment during his or her lifetime, attended special classes or a special school, or received special help at school in the past 12 months. Whether or not the child had a problem, the parent reported if the child had received routine or sickness or injury care in the past 6 months from any clinic, health center, hospital, or doctor's office.

Depression was evaluated using the Children's Depression Inventory,[20] a 27-item child self-report measure of symptoms over the past 2 weeks. Examples of symptoms are low self-esteem, poor concentration, insomnia, and a desire to commit suicide. A score above 9 is indicative of the need for psychiatric evaluation.[20] Behavioral problems were assessed using the Child Behavior Checklist.[21] This 118-item scale relies on parental report of child behavior over the past 6 months and is norm-referenced for large populations within and outside the United States. A *T* score equal to or above 60 on the total behavior scale corresponds to the 82nd percentile, the borderline clinical range warranting further evaluation. Given the residential instability and lack of structured social groups available to many homeless children, the social competence scale of the Child Behavior Checklist was not performed.

Receptive vocabulary was measured with the Peabody Picture Vocabulary Test.[22] The child was asked to point to one of four pictures that describes the spoken word best. The total score was normed for age. Three reading skills—letter-word identification, word attack, and passage comprehension—were assessed using the reading subtest of the Woodcock-Johnson Language Proficiency Battery.[23] Total reading score was normed for age and grade. Scores at or below the 10th percentile for age were considered indicative of severe delay in receptive vocabulary and reading skills. Below the 10th percentile, a child would be receiving a letter grade of F and functioning at least one grade below grade level. Both instruments had standardized Spanish versions with norms for Spanish-speaking populations.

Data Analysis

Bivariate analysis of discrete variables was performed using a chi-square test of proportions, and analysis of continuous variables was performed using analysis of variance. Linear and logistic regression analyses were used to examine whether the child's homeless history variables and demographic factors (child's age, sex, and ethnicity; parent's age, sex, marital status, education, and income) were uniquely associated with each child mental health problem, and to determine whether specific child mental health problems were uniquely associated with service use, controlling for other factors. The regression models were used to generate predicted levels of need or service use for groups of interest, such as ethnic groups, controlling for all other demographic variables. The reference population for the analysis was all 6- to 12-year-old homeless children residing in the shelters during the study period. The data were weighted by the number of eligible children per family. The significance statistics and standard errors were adjusted for the correlations in responses for children from the same family by using the intraclass correlation model.[24,25]

Results

Eighteen of the 22 (82%) of the eligible shelters agreed to participate, representing all seven geographic regions of Los Angeles County. A shelter was eligible if it allowed homeless families to stay at least one night and was an emergency shelter with a length of stay of less than 60 days. Emergency homeless family shelters ranged from missions to publicly funded facilities. Interviews were completed on 118 of 121 (98%) eligible families and on 169 (100%) eligible children.

The majority (93%) of the homeless parents living with children were women from predominantly minority backgrounds. Their mean age was 34 years; one third (34%) were married; and their average education was 11 years. The majority of families (61%) were living in extreme poverty with an annual income of less than $10 000. The average number of children per family was 3.6, with a range of 1 to 10.

One half of the children were female, and most were from minority backgrounds (Table 1). Approximately 44% of the children were African American, 35% were Latino, 14% were White, and 7% were classified as Other. Fifty-five percent of children were between the ages of 6 and 9 years, and 45% were between the ages of 10 and 12 years (mean age = 9.2 years, SD = 2.0).

The average age the child first became homeless was 7.6 years, with no significant differences between ethnic groups. More than a quarter (26%) of the children had first become homeless more than a year ago, and more than half (52%) had been homeless for more than 2 months over the past year. Almost one half (46%) had lived in more than two places over the past 12 months, and 6% had entered back into homelessness more than twice in the past year after having had a home or stayed with family or friends for at least 30 consecutive days. Compared with children from other ethnic groups, Latino children were more likely to have been homeless for more than 2 months over the past year ($P = .001$), and non-Hispanic White families were more likely

*$P \leq .01$

to have lived in more than two residences over the past year ($P = .004$). Homeless history did not vary significantly by child's age or sex.

Most children (88%) were registered in school. However, 16% had missed more than 3 weeks of school over the past 3 months.

Thirty-seven percent of the children exceeded the cutoff point for depression requiring a psychiatric evaluation, and 28% scored in the borderline clinical range for a serious behavioral problem. The correlation between these scores was weak (Spearman $r = .27$). Parent and child demographics did not vary significantly between children with and without emotional and behavioral problems. Based on multiple logistic regression analyses, neither parent and child demographics nor the amount of time homeless nor the number of residences over the past 12 months predicted child depression or behavioral problems.

Forty-seven percent of homeless children scored at or below the 10th percentile in receptive vocabulary, and 39% had a severe delay in reading. That is, when asked to identify which picture corresponded to the spoken word, almost half the homeless children functioned at or below the lowest 10th percentile for children of the same age in the general population, and almost 40% demonstrated reading skills at or below the lowest decile, equivalent to an F letter grade. African-American children had significantly greater delays in receptive vocabulary ($P = .028$) and reading ($P = .001$) than homeless children from other ethnic groups, and this difference remained in the logistic regression analysis that controlled for homeless history, parental history of mental illness, and substance abuse. There were no other significant differences in parent or child demographics.

Among children requiring a psychiatric evaluation for depression, only a minority (23%) had ever received counseling or treatment in their lifetime, and even fewer (19%) had been in special education classes or received special help in school during the past 12 months (Table 2). Moreover, only 30% of those children with a behavioral problem had ever received any counseling or treatment, and even fewer (17%) had been in special education or received additional help in school in the past 12 months. Children with a behavioral problem, however, were more likely to have received counseling or treatment than those without a problem ($P = .001$). There was no significant difference in child age, sex, or ethnicity among those children receiving or not receiving any of these interventions. Only three children identified by a parent as having a problem had ever received medication for an emotional or behavioral problem, a developmental delay, or a learning disability in the past 12 months.

Likewise, only 14% of children scoring at or below the 10th percentile for age in receptive vocabulary had been in special classes or had received additional help in class during the past 12 months. Among children with a severe reading delay, only 19% had received any special education in the past year. Children with a severe reading delay, however, were more likely to receive special education than other children ($P = .001$).

Almost two-thirds (65%) of homeless children had visited a clinic, health center, hospital, or doctor's office for routine health care over the past 6 months, and fewer than half (46%) had received care

for sickness or injury within the same period. Children suffering from depressive symptoms or a severe reading delay were more likely than those without such problems to have visited a health care practitioner over the past 6 months ($P < .001$, $P = .01$).

Among the 78% of children with at least one emotional or academic problem, parents were aware of a problem for only one third of them. Moreover, of those children identified by a parent as having a problem, only one half had received any type of mental health or academic intervention.

Discussion

Most sheltered homeless children in Los Angeles County require clinical evaluation for serious emotional and behavioral problems and severe academic delays. The high prevalence of problems is alarming but not surprising, given that many homeless children not only possess multiple traditional risk factors for mental disorders, such as poverty, stress, and single-parent families,[26–33] but also experience stressors perhaps unique to being homeless, such as frequent moves and discontinuity in school at a relatively young age.

The sheltered homeless children studied here were almost 20 times more likely to have depressive symptoms than prepubescent children in the general population.[34] Clinical assessment of symptomatic homeless children is needed to determine whether their depressive symptoms correspond to a major mental disorder or are a response to the stress of being homeless, a transient phenomenon, or an artifact of the screening instrument. In an extensive literature review, we found few clues on the validity of the depression measure in low-income minority children.

Similarly, sheltered homeless children in our study were 1.5 times more likely to have symptoms of a behavioral disorder than those children in the measure's large normative general population. As noted elsewhere, race and socioeconomic status have little effect on scale scores of the Child Behavior Checklist,[21] so our finding is unlikely to be an artifact of the screening instrument.

Homeless children were also approximately four times more likely to score at or below the 10th percentile in receptive vocabulary and reading than children of similar age in the general population. That is, a substantial number of homeless children, although attending school, did not possess average grade-level reading and receptive vocabulary skills to allow them to learn competitively alongside their housed counterparts. Greater academic delays found among African-American homeless children could reflect a cultural bias in the testing instruments[35]; however, even when tested and scored in their preferred language, a high percentage of Latino children, as well as of non-Hispanic Whites, had serious academic delays. Both academic measures had large normative samples for English- and Spanish-speaking children.[22,23]

Yet despite this high need, we found that few homeless children receive treatment. Moreover, a target population of those children most likely to require services could not be identified; demographic characteristics and homeless history parameters did not predict child emotional disorders or academic delays, probably because of the high prevalence of problems and important predictor variables such as poverty status. Thus, service provision and not health screening appears to be the priority for school-age sheltered homeless children. Our study findings offer some insights into how such provision may be made.

Residential instability, a paucity of community mental health clinics, erratic school attendance, and the lack of parental awareness of a child's problem may make it particularly difficult for homeless children to receive services. Hence, mental health and academic interventions for homeless children should be adapted to accommodate the crisis nature of sheltered homeless families and include parental education and mechanisms for continued care once the family obtains stable housing. Furthermore, both the relatively high level of contact with a health care practitioner for routine general health care and the greater likelihood that depressed children receive care for sickness suggest that the general medical sector could be a potentially important point of contact for serving homeless children.

This study has two main limitations. One is the absence of a comparison group of low-income, housed, and predominantly minority children. However, a suitable control group, one that would have a similar distribution of risk and protective factors except for being homeless, could not be identified because of the unique and varying combinations of social and economic disadvantages among homeless families. The other limitation—the exclusion of nonsheltered homeless children—may have resulted in the prevalence of child problems being underestimated since the number of homeless families unable to obtain emergency shelter is estimated to be greater than the number of sheltered homeless families.[3] Furthermore, the study's cross-sectional design and age restriction prohibit conclusions about risk factors for behavioral problems and developmental delays among the larger homeless child population under 6 years of age.[36]

Despite these limitations, the prevalence of serious emotional problems and severe academic delays reported here suggests that programs for homeless children are needed, regardless of the level of need in any comparison group. The strength of our findings is supported by comparable results from earlier studies based in other major cities[9,11,12] and by a high participation rate from a diversity of emergency homeless shelters in a heavily populated metropolitan county. Mental health and educational services for homeless children should be a component of a comprehensive package of services that assist families in obtaining permanent housing. These programs could require participation of the schools, shelters, and routine health care practitioners, as well as inclusion of parental education. Without such timely intervention, however, the emotional and behavioral problems and severe academic delays of homeless children will go untreated, threatening the development of these children at a critical period in their lives and robbing them of the fundamental opportunity to gain the emotional tools and academic skills necessary for fully productive and independent lives. □

Acknowledgments

This research was conducted under the Robert Wood Johnson Clinical Scholars Program at the University of California at Los Angeles.

The authors would like to express their gratitude to the Robert Wood Johnson Foundation for its financial assistance; to Drs Robert H. Brook, M. Audrey Burnam, Arlene Fink, Steven Forness, Ralph Frerich, Milton Greenblatt, and Paul Koegel for their assistance in research design; to Barbara Genovese, Enrique Godinez, Marlene Nishimoto-Horowitz, Adam Oberweiser, Monica Paez, and Ruth Stearn for their diligent work collecting data; to Dr Barbara Leake at the University of California at Los Angeles and Dr Naihua Duan and Bernadette Benjamin at the RAND Corporation in Santa Monica, Calif, for statistical consultation; and to shelter staff and residents for their strong support and cooperation that made this study possible.

This paper is dedicated to the memory of Dr Howard E. Freeman, an outstanding mentor and teacher.

Risk Factors for Homelessness among Schizophrenic Men: A Case–Control Study

ABSTRACT

Objectives. To identify risk factors for homelessness among the severely mentally ill, we conducted a case–control study of 100 indigent schizophrenic men meeting criteria for literal homelessness and 100 such men with no homeless history.

Methods. Subjects were recruited from shelter, clinic, and inpatient psychiatric programs in Upper Manhattan. Clinical interviewers employed standardized research instruments to probe three domains of risk factors: severity of mental illness, family background, and prior mental health service use.

Results. Homeless subjects showed significantly higher levels of positive symptoms, higher rates of a concurrent diagnosis of drug abuse, and higher rates of antisocial personality disorder. Homeless subjects experienced greater disorganization in family settings from birth to 18 years and less adequate current family support. Fewer homeless subjects than subjects in the never-homeless comparison group had a long-term therapist. These differences remained when demographic variables were adjusted statistically.

Conclusions. Homeless schizophrenic men differed from their domiciled counterparts in all three domains we investigated; family background, nature of illness, and service use history. Findings are discussed in relation to policy and programs for the severely mentally ill. (*Am J Public Health.* 1994;84:265–270)

Introduction

A recent governmental report estimates that 1 in 20 of the severely mentally ill experience homelessness.[1] Using different definitions of homelessness or housing instability, empirical studies of state mental hospital constituents have found that from 9% to 28% have been homeless.[2–4] The crisis nature of homelessness, both for the individual and for society, demands a clearer understanding of why some of the severely mentally ill become homeless while others do not.

Previous studies in which differences between the homeless and the residentially stable have been explored suggest that the homeless have more psychiatric disorders meeting standard diagnostic criteria[5,6] and higher rates of hospitalization and arrest.[5,7] Studies focused on defined psychiatric populations have found that the homeless are more likely to abuse alcohol[3,8] and/or drugs,[3,4,6] have higher symptom levels,[3,7,8] and are less likely to comply with prescribed treatments.[3,8] The use of different definitions of homelessness, the employment of varied approaches to the assessment of psychiatric disorder, and the selection of different subgroups of the homeless population in these investigations limit their generalizability.

Attempts to identify areas of differences between the homeless and the never homeless outside of the illness domain are more limited. Studies of childhood antecedents of adult homelessness have revealed that homelessness (or its duration) is associated with placement in foster care[9,10] or group homes,[10] physical abuse,[9] and runaway episodes.[10] Although the breakdown of family ties has been thought to play a role in the genesis of homelessness, perceptions of the kinship bond in adulthood have not been found to be as important as patient characteristics in distinguishing the homeless from the nonhomeless.

In spite of the discourse on deinstitutionalization of mental health services as a possible factor in homelessness among the severely mentally ill,[11,12] the service use histories of homeless and never-homeless persons have not been compared with regard to access to and utilization of community-based treatment and support services. Although the literature suggests that multiple factors may separate the homeless from the never homeless, there has been no prior attempt to incorporate multiple risk factors into a single study.

We recently completed a case–control study of indigent schizophrenic men in New York City designed to test hypotheses about differences between the homeless and never-homeless mentally ill. To facilitate an adequate test of hypotheses about differences between the homeless and never homeless, we elected to focus our study on a homogeneous group of indigent adults suffering from schizophrenia. Schizophrenia is the most common diagnosis leading to chronic mental illness[13] and is widely prevalent among those living in shelters.[1,14,15] Because four of five homeless adults are male,[16] it is

possible that pathways to homelessness are gender-specific. Therefore, our sample was stratified by gender. Findings from our study of women will be reported later.

We probed three domains of influence on homelessness: severity of illness, family background, and prior mental health service use. We hypothesized that schizophrenic men who became homeless would have poorer pre-illness social functioning, higher levels of the positive and negative symptoms of schizophrenia, greater abuse of drugs and alcohol, and more antisocial personality disorder. In addition, we hypothesized that the homeless would have experienced greater family disorganization in childhood, would have imposed a greater caretaker burden after becoming mentally ill, and would have less current family support. Finally, we hypothesized that the homeless would be less adherent to prescribed treatment and would have less help from the mental health system in finding adequate housing and procuring long-term follow-up care.

Methods

We employed a case–control design with 100 men in the (sheltered) homeless group and 100 men in the never-homeless group. All 200 subjects had experienced at least one psychiatric hospitalization and were between the ages of 18 and 44 years. To be eligible for inclusion, the men were required to meet DSM-III-R criteria for schizophrenia or schizoaffective disorder, determined through a research diagnostic interview, the Structured Clinical Interview for DSM-III-R (SCID).[17] Voluntary informed consent was elicited from each subject after a treating clinician attested to the subject's ability to fully comprehend the implications of participation in our research.

Case subjects met criteria for literal homelessness, meaning that they had no fixed abode and were forced to sleep in the street or in shelters.[18] They were recruited by a mental health day treatment program located on-site at a municipal shelter for homeless men in Upper Manhattan.

Control subjects had no lifetime history of literal homelessness, as determined by a screening instrument.[4] They were discharge-ready inpatients or outpatients recruited from Columbia University–affiliated psychiatric services in Upper Manhattan. More than four of five control subjects resided in a family setting, usually with a parent or sibling.

Because Blacks have been found to be overrepresented among the sheltered homeless in New York City,[19] we made every effort to match case and control subjects on ethnicity (Black, White, Hispanic). When we encountered difficulty in finding an adequate number of Black subjects who had never been homeless, we abandoned our matching strategy. Reasons for the paucity of Black never-homeless subjects constitute a topic in need of further study.

A total of 248 men were asked to participate in the study. Eleven (4.4%) refused, and 22 (8.9%) dropped out before completing the interview battery. Four of five dropouts were homeless men who precipitously left the shelter without letting the mental health staff know how to reach them. Fifteen (6.1%) of the homeless subjects with completed interviews were eliminated from the study because of inconsistent or poor-quality data that could not be improved with a reinterview. In such cases the subject was either too delusional or too disorganized to function as a reliable informant. It is possible that the more disturbed subjects were not included in the final sample.

Subjects were interviewed by mental health clinicians specially trained to administer the assessment battery. Clinical and anamnestic data were verified with information contained in the clinical case record. A family member was also interviewed for 57% of the homeless and 68% of the never homeless. The most common reason for the lack of a family interview was the subject's estrangement from kin.

Instruments

The following research instruments were used to assess key study variables:

Pre-illness social functioning was rated with the Los Angeles Social Attainment Scale, a seven-item instrument focused on peer relationships and social participation in late adolescence.[20] The alpha reliability coefficient for this scale is .80.

The positive (active psychotic symptoms such as delusions, hallucinatory behavior, and conceptual disorganization) and negative (deficit symptoms such as blunted affect, emotional withdrawal, and difficulty with abstract thinking) dimensions of schizophrenia were assessed with the Positive and Negative Syndrome Scale, a 30-item rating scale evaluating symptoms present during the 7-day period prior to the interview.[21] The alpha reliability coefficient was .79 for the positive scale, .84 for the negative scale, and .83 for the general psychopathology scale.

Current and lifetime alcohol and drug abuse or dependence were evaluated with the SCID, which yields information on the extent to which heavy use of alcohol or seven classes of drugs meets criteria for a diagnosis based on standards commonly applied in psychiatry.[17]

Antisocial personality disorder was evaluated with the SCID-II, the segment of the SCID dealing with personality disorders.[17] This instrument probes the presence of conduct problems—such as running away from home, being truant from school, initiating physical fights, or belonging to a gang—occurring before the age of 15, as well as patterns of irresponsible, destructive, or illegal activity carrying over into adulthood. For a subject to meet criteria for a diagnosis of antisocial personality disorder, a conduct disorder must have been present in early adolescence.

Family disorganization in childhood was evaluated with 4-point rating scales contained in the Community Care Schedule.[22] These ratings are based on carefully defined anchor points for the assessment of nurturing constancy, residential stability, adequacy of income, dependence on public assistance, family violence, parental criminality, parental mental illness, and parental substance abuse—the components of an index of family disorganization. Information for this instrument was elicited from both the subject and a family member (whenever possible) to obtain the most complete picture of family life during the subject's childhood. The alpha reliability coefficient for the seven-item index of family disorganization is .69.

Current family support was rated on a scale of adequacy, based on the degree of support and assistance available from family members regarding money, shelter, food, clothing, advice, and companionship.[22] Information for this rating was obtained from the subject and corroborated by a relative when possible.

Caretaker burden was assessed with a semistructured interview that yielded a 3-point rating of overall burden.[23] Unlike other family variables, family burden required an assessment from a family member with firsthand knowledge of the family experience of living with the patient. Family burden data were missing for one third of never-homeless and nearly one half of homeless case subjects.

Prior service use was explored with items contained in the Community Care Schedule[22] that were designed to elicit detailed information on medication adherence patterns, long-term follow-up care, and housing placement at hospital discharge. Medication adherence was rated on a 4-point scale on the basis of the sub-

ject's self-report. Long-term follow-up care was defined in terms of the number of months in outpatient treatment with the same therapist.

Statistical Methods of Analysis

The case subjects (homeless) were compared with the control subjects (never homeless) with respect to three classes of key variables. In the illness domain, there were six variables: premorbid social attainment scale, positive symptom score, negative symptom score, and binary indicators of alcohol abuse, drug abuse and antisocial personality disorder. In the family domain, there were three variables: family disorganization index, adequacy of family support, and assessment of burden. In the service use domain, there were two variables: medication adherence and existence of a long-term therapist.

First we compared the case and control subjects without taking into account sampling characteristics of the groups, and then we compared them after making statistical adjustments for demographic variables that could possibly account for observed differences. Statistical adjustments were made by means of logistic regression, with the binary case/control variable treated as the outcome and the risk variables and possible confounders treated as explanatory variables. Possible confounders were chosen from those demographic variables shown in Table 1 that were at all related to the case/control variable (at the $P < .15$ level). These included place of birth, New York City residence history, ethnicity, and veteran status. We did not adjust for current income variables, because they can be expected to be related to homelessness structurally rather than incidentally.

To facilitate the comparison of adjusted and unadjusted associations between the risk variables and the case/control distinction, we presented both using results from logistic regression analyses. The test statistic we present is the likelihood ratio chi-square from the logistic analyses.[24] For the unadjusted case/control comparisons the pattern of significance results from the likelihood ratio chi-square is the same as would be obtained by means of t tests or Pearson chi-square statistics.

Results

Demographic Profile

The homeless (case) group and never-homeless (control) group had many traits in common, including median age (32 years); marital status (four fifths had never married or were currently single); median level of education (11 years); and employment status (more than four fifths were unemployed). Moreover, most (89% of the homeless and 76% of the never homeless) were members of ethnic minorities. However, there were more Blacks among the homeless (66% vs 22%) and more Hispanics among the never homeless (54% vs 23%). Ethnic differences were reflected in differences in religious background (Catholics predominated among the never homeless, whereas Catholics and Protestants were nearly equally represented among the homeless) and place of birth. Nearly twice as many never homeless as homeless (39% vs 21%) were foreign-born.

Both groups were heavily dependent on public assistance. Nearly four fifths of the never homeless and three fifths of the homeless were receiving income from entitlements, averaging about $430 per month. Thirteen percent of the never homeless and 19% of the homeless earned an average of $100 per month at unskilled jobs. Thirty-three percent of the never homeless and 8% of the homeless also received some financial support from their families. For subjects who had ever worked, the longest duration of steady employment was an average of 12 months. Unemployed subjects had been out of work for an average of 4 to 5 years. Nine percent of the never homeless and 22% of the homeless had served in the armed forces.

Family History and Illness Onset

Thirty-five percent of the never homeless and 23% of the homeless had lived with both biological parents from birth to 18 years of age. The majority in both groups experienced one or more changes in the primary nurturing adult in childhood and adolescence. One fourth of the never homeless and more than one third of the homeless had experienced two or more such changes. One never-homeless subject and six homeless subjects experienced foster care placement; four homeless subjects had been placed in a group home. Four never-homeless subjects and 20 homeless subjects had a father, mother, or sibling with a history of homelessness.

The median age of onset of psychiatric disorder was 21 years for the never homeless and 20 years for the homeless. Never-homeless subjects experienced their first psychiatric hospitalization at a median age of 22 years; for homeless subjects it was 21 years. Most subjects had extensive hospitalization histories. Fifty-eight percent of the never homeless and 56% of the homeless had been hospitalized in the 12-month period preceding the

interview. The median number of hospital days in this time period was 60 for the never homeless and 43 for the homeless subjects. At the termination of the most recent hospitalization episode, 11 homeless subjects and 1 never-homeless subject had been discharged against medical advice. Ninety-six percent of the never homeless and 83% of the homeless had been given a recent prescription for neuroleptic medication (the class of psychotropic drugs often used to treat schizophrenia).

Subjects with substance abuse problems had initiated alcohol and drug use in midadolescence. The median age of onset of drug abuse (any drugs) was 18 years for never-homeless subjects (44%) and 16 years for homeless subjects (77%). The median age of onset for alcohol abuse was 18 years for both groups (44% of the never homeless and 49% of the homeless). Fifteen percent of the never homeless and 34% of the homeless had received some form of substance abuse treatment in the 12-month period preceding the interview.

Thirteen percent of the never homeless and 46% of the homeless had had severe conduct problems before the age of 15 years. Six percent of the never homeless and 28% of the homeless reported that they had run away from home at least once during early adolescence. Nine percent of the never homeless and 42% of the homeless were given a research diagnosis of adult antisocial personality disorder, and 25% of the never homeless and 72% of the homeless had jail or prison histories.

Distinctions between the Homeless and the Never Homeless

Table 2 summarizes tests of study hypotheses about the differences between never-homeless and homeless schizophrenic men. The tests are presented in two forms, one that is unadjusted for possible case–control differences that may confound the group comparisons and one that adjusts for demographic factors that may be related to selection into the study.

Within the illness domain, there were no significant differences between the homeless and the never homeless on the Los Angeles Social Attainment Scale scores in either unadjusted or adjusted tests. Average ratings on peer socialization and social participation in late adolescence were at the "poor premorbid" level in both groups. Homeless subjects did show significantly higher levels of positive symptoms than did the never-homeless subjects ($P < .01$, unadjusted; $P < .05$ adjusted). However, there were no major differences in negative symptom levels. There were no meaningful differences in the proportion of subjects in each group with a concurrent diagnosis of alcohol abuse, but a significantly larger number of homeless subjects had a concurrent diagnosis of drug abuse ($P < .01$ for both unadjusted and adjusted tests). Similarly, a significantly larger number of homeless subjects had a concurrent diagnosis of antisocial personality disorder ($P < .01$ for both unadjusted and adjusted tests).

Within the family domain, the mean score on the index of family disorganization was higher, indicating greater impairment, for homeless subjects ($P < .01$, unadjusted; $P < .05$, adjusted). Family support was less adequate for the homeless ($P < .01$ for both tests). However, there were no significant differences in the overall levels of caretaker burden.

In terms of service use issues, the homeless initially appeared to adhere less to prescribed medication regimens ($P < .01$, unadjusted), but that difference did not withstand adjustment for potential confounders ($P < .10$). Fewer homeless subjects had a long-term therapist, an indicator of continuity of care ($P < .01$, both adjusted and unadjusted).

At discharge from the most recent psychiatric hospitalization, 50% of the homeless (undomiciled before hospitalization) were discharged to a shelter or the streets. The 95% confidence interval for the proportion P is between 40% and 60%.

Table 2 shows how each of the individual risk variables relates to homelessness after demographic factors that might be related to selection are controlled. We carried out additional analyses to determine the extent to which these variables accounted for the same variation in the homelessness distinction. When all the risk variables in Table 2 were entered simultaneously in a logistic model fitting log odds of homelessness (along with the demographic control variables), one variable in each domain remained either significant or a trend. Still significant by the Wald statistic were drug abuse (from the illness domain) (Wald = 5.28, $df = 1$, $P < .05$)

and adequacy of family support (from the family domain) (Wald = 14.41, $df = 1$, $P < .001$), whereas having a long-term therapist (from the service use domain) was reduced to a trend (Wald = 3.07, $df = 1$, $P < .10$). These three variables seem to reflect different aspects of the differences between the homeless and never-homeless groups.

Two variables under the illness domain that are significant in Table 2 are not significant when adjusted for the other risk variables. Positive symptoms is no longer a discriminating variable when other illness domain variables are controlled, but antisocial personality disorder loses significance only when adequacy of current family support is adjusted.

Adequacy of family support also appears to be the variable that accounts for the effects of family disorganization index and having a long-term therapist. These variables are significant in Table 2, but they do not appear to differentiate the homeless from the never homeless when adequacy of family support is adjusted.

Discussion

In this study we have attempted to identify factors that differentiate economically disadvantaged schizophrenics who live in private homes from those who are homeless and who live in public shelters. Although not definitive in terms of causal pathways, a case–control design such as ours is an efficient way to spot potential risk factors for homelessness. Some variables we explored preceded the first homeless experience and may play a causal role. In addition to childhood antecedents, our data indicate that drug abuse and antisocial personality disorder had their onset prior to homelessness. The cross-sectional nature of our study prevents us from determining whether other variables are a cause or a consequence of homelessness. Our data show an association between family disorganization in childhood and poor family support in adulthood in assessing the risk of homelessness. However, a longitudinal approach is needed to establish that breakdown of family relationships plays a causal role in homelessness.[7] Higher current levels of positive symptoms and the lack of a long-term therapist could be either a cause or a consequence of homelessness. Higher symptom levels can precipitate behaviors that undermine housing stability, but the vicissitudes of street or shelter living can increase distress and disrupt usual patterns of mental health care. Our data on hospital discharge practices for homeless subjects suggest that the pattern of discharging patients to shelters or streets functions to perpetuate homelessness.

The sampling design of our study formally limits us to generalizing our findings only to persons who have the same demographic and clinical characteristics as our study subjects and who are enrolled in mental health treatment programs similar to those from which we drew our sample. However, the pattern of findings suggests that they may be more general, particularly among the severely mentally ill. We found that the homeless schizophrenic men differed from their domiciled counterparts in all three domains we investigated; family background, nature of illness, and service use history.

Schizophrenic men who came from families with high levels of family disorganization, characterized by lack of nurturing constancy, residential instability, economic inadequacy, dependence on public assistance, family violence, mental illness, substance abuse, or criminality in a parent, were more likely to be in the homeless group than in the never-homeless group, even when demographic variables such as place of birth and ethnicity were controlled. Our findings broaden the scope of childhood antecedents of adult homelessness to include family economic problems and parental pathology, the latter being strongly associated with out-of-home placement.[25] However, the logistic regression analysis revealed that poor family support is a more important risk factor for homelessness than childhood antecedents. We thought it reasonable to ask whether the overall burden experienced by the family in taking care of the schizophrenic relative might differentiate the homeless from the never homeless. Our negative findings should be interpreted cautiously because our ability to measure family burden was limited.

The men who ended up in our homeless group do appear to have a strikingly different profile of psychopathology. They were more likely to have positive symptoms of psychosis and to have concurrent drug abuse and antisocial personality disorder. The logistic regression analysis revealed that drug abuse was the most important risk factor in the illness domain. There were no significant differences between the homeless and the never homeless in premorbid social adjustment, negative symptoms, or alcohol abuse. Thus, the homeless in our study were not more severely ill in all dimensions of psychopathology.

The finding that 50% of the homeless (undomiciled before hospitalization) were discharged to a shelter or the streets indicates that the homeless in our study had less access to adequate care. Although this finding may reflect local mental health practices, similar findings have emerged from studies carried out in Chicago[26] and rural Ohio.[27] The logistic regression analysis revealed that the most important risk factor in the service use domain was not having a long-term therapist. Future work will have to determine whether lack of a long-term therapist is an access problem or a consequence of resistance to treatment.

Clearer identification of risk factors for homelessness can lead to the development of preventive intervention strategies. For example, thorough assessment of patterns of substance use, family support, and prior outpatient service use in concert with routine discharge planning can identify those who require additional services and supportive housing. Patients with co-disorders can be singled out for intensive case management to improve the successful coordination of mental health and substance abuse treatment services.[28–31] Finally, although risk factors aid in identifying those individuals most vulnerable to homelessness, they do not obviate the need for policymakers at all levels of government to address the chronic shortage of affordable housing for indigent Americans. □

AIDS, HIV Infection, and Illicit Drug Use within Inner-City Families and Social Networks

ABSTRACT

Objectives. Drug use is commonly depicted and treated as an individual problem. This study describes the extent of drug use, human immunodeficiency virus (HIV) infection, and acquired immunodeficiency syndrome (AIDS) among drug users' sexual partners and family and household members in order to broaden considerations of risk.

Methods. Social network charts and structured interviews were administered to 126 women (predominantly African American and Latino) enrolled in methadone treatment. The charts elicited the prevalence of drug use and HIV infection among subjects' family and household members.

Results. Drug use and HIV/AIDS permeated subjects' sexual, familial, and household relationships. More than half of the women who resided with a sexual partner reported that their partners currently used drugs. Almost one third of the subjects' siblings were drug users. Of the 715 total siblings (all subjects plus their siblings), 69 (9.7%) were known to be HIV positive or to have an AIDS diagnosis.

Conclusions. The sexual, familial, and household expressions of drug use underscore the notion that drug use and attendant risks, including but not limited to HIV infection, might be usefully viewed and treated as an inter- and intracommunity problem rather than as an exclusively individual one. Introduction

The identification of illicit drug use, first intravenous heroin and cocaine and more recently crack (a smokable cocaine derivative), as behavior associated with increased risk of human immunodeficiency virus (HIV) infection has resulted in a body of research that includes the study of individual behaviors in the transmission of HIV in addition to factors that are exclusively biological.[1–7] Because individual human behavior originates in and is perpetuated through social activities and cultural contexts, studies of high-risk behaviors such as needle sharing and unprotected sex suggest the need to further broaden our notions of risk to include the social and cultural aspects of drug use in people's lives.[8,9] This understanding might then inform the development of culturally appropriate and socially effective interventions that address the problems of drug use, HIV infection, the acquired immunodeficiency syndrome (AIDS).

This paper represents an effort to characterize several important aspects of the social environment in which many drug-using women live (in this case, poor methadone patients in the Bronx). Epidemiological studies and case reports of the prevalence of HIV/AIDS in this area,[10] as well as the prevalence of HIV infection in the methadone program from which our subjects were drawn,[5] suggested the value of a closer examination of these women's family and social networks. This study was undertaken to explore the relationships between drug use, HIV infection, and social networks, including family members, sexual partners, household members, persons at risk of HIV infection, and friends.

The study was conducted from 1988 to 1990 in a methadone maintenance clinic administered by a teaching hospital in the Bronx, New York. The methadone program, which serves 700 patients, includes the administration of methadone (a substitution treatment for people with histories of opiate addiction), counseling services, an HIV testing and counseling program, and primary health care.

The fieldwork for the study was conducted through the Women's Center, a peer support program operating in the drug treatment program. Created in 1987, the Women's Center program includes support groups that provide women in methadone treatment with an opportunity to speak freely in a group setting about drug use, HIV infection, and personal matters. The program also serves as a field station for research related to social and cultural aspects of drug use, HIV infection, and HIV transmission.

Methods

The study is based on in-depth interviews with 126 women in methadone treatment. The first 30 subjects were participants in the weekly Women's Center peer support group. The remaining 96 were referred from the methadone clinic population by the original 30 subjects, by

[a]Significance of association between subject's and partner's use of drug.

clinical staff, and by methadone counselors. After their interviews, women not previously in the support group were invited to join as part of their HIV prevention education.

Interviews lasted for 2 hours. Each began with the administration of a kin-chart sociogram (charting kinship and social relations), followed by questions covering demographic items, history of drug use and reproduction, and HIV status. In addition, in completing a mother–child coresidence history, the interviewer inquired about the periods of time during which each woman's children had and had not lived with her, the reasons for separations, a description of both the child's and the mother's relationship to the people with whom the child lived during separation, and whether custody was informal, temporary, or legal.

The charting of kinship and social relations used in this study has its origin in classical anthropological studies of kinship.[11] In this charting method, structured with the study participant as the point of reference and stratified by generation, a model is constructed of a subject's kin relations, starting with those in closest biological or social proximity and moving outward to include persons more and more distantly related.

Similarly, in this study, the investigator initiated the construction of a kin-chart-sociogram by asking each subject a sequence of questions designed to identify blood relatives and those related to the subject through marriage. Beginning with the subject's siblings and progressing through all relatives with whom the subject was personally acquainted, the chart was completed with the identification of the subject's drug-using and non-drug-using associates and friends. Once all of these individuals had been identified and their genders, ages, places of residence, and HIV status (if known) noted, they were assigned attributes. These attributes included drug use and type, friend, sexual partner, household member, member of children's household (if children were residing separately from their mother), serostatus, and knowledge of the subject's serostatus.

Data analyses involved comparisons of proportions. Chi-square tests or, in the case of small numbers, Fisher's Exact Tests were used to determine the two-tailed statistical significance of associations. An alpha level of .05 was used as the indicator of statistical significance. The data were analyzed with SAS software.

Results

Population Characteristics

The population characteristics of the subjects are shown in Table 1. The concentration of ethnic minorities and women on public assistance is noteworthy.

Drug use. Despite their enrollment in a methadone program, 72% of the women in the study reported current illicit drug use. Twenty-five percent of the current drug users reported polydrug use. Crack was more frequently reported to be used on a daily basis (71% of the 41 users) than were either heroin (30% of the 30 users) or injected cocaine (28% of the 43 users), $\chi^2 = 18.808$, 2 *df* ($P < .001$).

HIV serostatus. Eighty-four percent of the 126 women reported having been tested for HIV infection. Of these, 48% stated that they were HIV positive, 43% stated that they were HIV negative, and 9% stated that they did not know their test results.

Household composition. Subjects reported six principal household membership patterns (see Table 2). Most of the women lived with a family member or members (including children and sexual partners), and half lived with at least one of their children. Only 11% lived alone.

Sexual partners. Half of the women reported living with a sexual partner. Most of these (82.5%) lived with a male partner, and 17.5% lived with a female partner.

Mothers and children. At the time of the interview, 106 women had 250 children under 18 years of age, half of whom were living with their mothers.

The Social Context of Drug Use

Subjects and coresiding sexual partners. Seventy percent of the 63 women in residence with a sexual partner reported that they regularly used illicit drugs and that 57% of their partners did so. Although only a minority of the partners (<25%) used crack or other forms of cocaine, significant positive associations were found between women's use of crack and other forms of cocaine and that of their partners. This pattern differed from that of heroin users; no significant association was found between women's current use of heroin and that of their coresiding sexual partners (see Table 3).

Children and household drug use. Drug use was common in the households with children under the age of 18: of the 142 children who resided with their mothers, 64.8% lived with a mother who reported regular use of illicit drugs, 82.4%

lived with at least one parent who used drugs, and 86.6% lived in households where at least one adult household member was a drug user.

History of drug use in subjects' families of origin. Histories of drug and alcohol abuse were reported in a minority of the women's parents. Among 240 known parents, 7.17% were reported to have abused alcohol and 7.9% were reported to have histories of illicit drug use.

Illicit drug use was widespread among subjects' siblings. One hundred twenty-six women in the study reported a total of 589 siblings (mean = 4.7; range = 0 to 20). Of the 119 women who had one or more siblings, 70.6% reported that at least one had a history of illicit drug use.

Of the 589 siblings, 30.6% were reported to have a history of drug abuse, not including alcohol. Eighty-five percent of these drug-using siblings were reported to have used heroin, some form of cocaine, or both. Only 6.3% of the subjects reported having a sibling who abused alcohol.

HIV Infection

Shared knowledge of positive serostatus. Among the 23 HIV-positive women with coresiding sexual partners (17 male partners and 6 female partners), 87% reported having informed their sexual partners of their serostatus. Seventy-five percent of the 40 HIV-positive women whose mothers were alive at the time of the interview reported having informed their mothers of their serostatus. Of the 27 HIV-positive women who knew their fathers and whose fathers were alive at the time of the interview, 48.1% reported having informed their fathers of their serostatus. Of the 47 HIV-positive women with siblings, 63.8% had shared their serostatus with at least one of their siblings and 34.0% had shared their serostatus with all of their siblings.

Serostatus and drug use. HIV-positive (n = 50) and HIV-negative (n = 46) women were compared in terms of type of drug used and frequency of use. Significantly more HIV-positive women (46%) than HIV-negative women (24%) reported current use of crack (chi-square test; $P < .03$). No other significant differences in drug use patterns were noted.

HIV infection in households. The presence of HIV infection in this population can be described in the context of the subjects' households. Forty-five percent of the 119 households were reported to have at least one member (including our subjects) who was HIV infected. Among these 54 households, 33.2% of the 202 household members were reported to be HIV infected (43 households included 1 HIV-infected person, 9 households included 2, and 2 households included 3).

Seventy-one children younger than 18 years lived in 50% of the 54 households with HIV-positive members; 7% of these 71 children were reported to be HIV infected. All were AIDS diagnosed.

HIV infection among siblings. Of the 715 total siblings (all subjects plus their siblings), 9.7% were reported to be HIV infected.

HIV infection, AIDS, and death by violent means. The subjects reported lifetime knowledge of 105 people living with HIV infection, 63 AIDS deaths, and 44 deaths by violent means among a total of 5053 known relatives of all ages. (Subjects were asked to identify family members who were HIV infected and those who were diagnosed with or had died of AIDS. In addition, in the course of constructing the kinchart-sociograms, women volunteered information about relatives who had died by violent means, including accidental death by fire, drowning, electrocution, or motor vehicle accident; homicide; drug-related deaths [overdose]; and suicide.) These HIV infections, AIDS deaths, and violent deaths were reported from among subjects, siblings, husbands, lovers, children, nieces, nephews, aunts, uncles, siblings-in-law, cousins, ex-husbands, ex-siblings-in-law, and stepparents.

Discussion

Drug Use

All data regarding drug use of the respondent or of her family or partner relied entirely on her own report, a clear limitation of the study. We consider it likely that such use was underreported rather than exaggerated. Comparable rates, at least of cocaine use, have been previously described among the same clinic population.[12]

Within subjects' families of origin, almost one third of the subjects' siblings were drug users. The relatively low number of drug users among parents (<8%) in comparison with the high number of their offspring who were drug users (>42%) suggests a marked increase in drug use between generations.

The social character of drug use is further evident in the number of households in which one or more member was a drug user and the number of children growing up in these households. The widespread presence of drug-using adults in households with minor children supports a perception of drug use and related behavior as normative.[13,14]

Drug use among sexual partners illustrates its relational character. All of the women who lived with a crack-using partner used crack themselves. The positive association of women's cocaine and crack use with their partners' use of the same drugs suggests some of the difficulties drug-using women may have when they try to stop using cocaine or crack.

HIV Infection

The familial and residential impact of HIV infection among African-American and Latino inner-city residents is reflected in our data in the number of subjects, subjects' relatives, and household members infected with HIV. The generational character of the HIV epidemic in New York City is reflected in the high number of infected siblings (largely of the subjects' generation).

The number of HIV-positive women who had shared knowledge of their serostatus with sexual partners and other family members suggests the persistence of familial intimacy. It also emphasizes the need for supportive services, not only for those who are HIV infected but for their family members as well.

The impact of the AIDS epidemic is reflected in our data through the number of persons reported to be HIV infected, which, according to the reports of our subjects, far exceeds the cumulative number of deaths attributed to violence throughout their lifetime.

Conclusions

The development of risk reduction strategies might profitably involve individuals or groups from drug users' social environments and communities, including active drug users and their organizations (as in Europe and Australia), for the purpose of community education, prevention, and support.[15,16] Meaningful employment may also contribute to decreased drug use by providing alternate social networks and enhanced self-esteem.

Finally, these findings encourage the provision of intensive and extensive primary prevention services, improved access to health care, and drug treatment options that incorporate the social nature of drug use and its expression in sexual relationships, households, families, and communities. □

Injecting Risk Behavior among Drug Users in Amsterdam, 1986 to 1992, and Its Relationship to AIDS Prevention Programs

Erik J. C. van Ameijden, MS, Anneke (J) A. R. van den Hoek, MD, PhD, and Roel A. Coutinho, MD, PhD

ABSTRACT

Objectives. Serial, cross-sectional trends in injecting risk behavior were studied among drug users from 1986 to 1992.

Methods. From a cohort study in Amsterdam, 616 intake visits of drug users who had injected in the 6 months preceding intake were selected.

Results. The proportion of drug users who reported borrowing and lending used injection equipment and reusing needles/syringes (in the previous 6 months), continuously declined from 51% to 20%, from 46% to 10% and from 63% to 39%, respectively. In multivariate analysis, it appeared unlikely that a selective recruitment of participants over time was responsible for these trends. Participants, recruited later in time, had been previously tested for human immunodeficiency virus (HIV) more often, had received daily methadone less often, and had obtained a higher proportion of new needles via exchange programs. Indications were found that (1) voluntary HIV testing and counseling leads to less borrowing, lending, and reusing equipment; and (2) obtaining needles via exchange programs leads to less reusing needles/syringes. It appeared that nonattenders of methadone and exchange programs have reduced borrowing and lending to the same extent as attenders.

Conclusions. Methodologically, evaluating specific measures is difficult. However, the combination of various preventive measures in Amsterdam is likely to be responsible for the observed decrease in injecting risk behavior. (*Am J Public Health.* 1994;84: 275–281)

Introduction

In several studies among injecting drug users in Amsterdam, prevalence of the human immunodeficiency virus (HIV) was estimated to be 30% and appeared to be stable from 1986 to 1992.[1–4] In a cohort study in Amsterdam, HIV incidence initially declined from 10 per 100 person-years in 1986 to 4 in 1987 and remained stable up to 1991.[5]

However, trends in HIV prevalence and incidence are difficult to interpret. First, HIV prevalence is the result of many complex mechanisms—for example, the geographical migration of injecting drug users; the high rates of initiation and cessation of injecting drug use; the high acquired immunodeficiency syndrome (AIDS) and non-AIDS mortality, both of which are largest among HIV positives[6]; and the HIV incidence. Second, HIV incidence in itself is also influenced by various factors—for example, HIV prevalence, mixing patterns,[7] and risk behavior; thus, to estimate HIV incidence, large cohorts of drug users are necessary, and because of specific methods of recruitment and relatively high dropout rates, generalization of incidence is difficult.

Therefore, to monitor the HIV epidemic among injecting drug users, it is important to study trends in risk behavior. And among this population, the sharing of injecting equipment is the predominant route by which HIV is transmitted. Moreover, if the effect of a prevention program aimed at reducing injecting risk behavior is to be evaluated, the extent to which the sexual transmission of HIV influences the prevalence and incidence of the virus among injecting drug users must also be considered.

In Amsterdam, easily accessible methadone programs and a large-scale needle/syringe exchange program have been implemented within the concept called harm reduction[8] (see Methods). In the cohort study in Amsterdam, early results (follow-up was conducted from 1986 to 1988) indicated that the borrowing of used injection equipment decreased only as a function of the number of follow-up visits but not at intake visits over time.[9] Therefore, this risk reduction was attributed mainly to participation in the study. Several other studies have shown that injecting drug users are capable of reducing risk behavior,[10,11] but only a few have presented data on long-term trends.[12,13]

The present study is an update of the Amsterdam cohort study mentioned above. In that same study, only data measured at intake visits were used to determine serial, cross-sectional trends in injecting risk behavior from 1986 to 1992 among participants who, at entry, reported current injecting. The high-risk behaviors studied were borrowing and lending used injection equipment, and reusing needles/syringes. We also extended the present study to evaluate the potential protective effects on risk behavior of HIV antibody-test counseling, methadone treatments, and the obtaining of new needles via exchange programs.

Methods

AIDS Prevention among Drug Users in Amsterdam

The specific purpose of the Amsterdam harm reduction approach is to create a situation that greatly reduces the risk of addicts harming themselves or their environment.[8] Within this context, three main measures were established to slow down the spread of HIV: (1) a needle and syringe exchange program (in 1984), (2) an information campaign targeted at drug users (in 1987), and (3) a program to distribute condoms (free of charge) among addicted prostitutes (in 1987).

The goal of the exchange program, begun through an initiative of the "junkiebond" (drug users organization) to prevent the spread of hepatitis B, is to prevent HIV infections by promoting the single use of needles and syringes and ensuring the availability of new needles. Equipment can be exchanged at methadone posts and other drug-help organizations (14 locations in 1991), and leaflets concerning safe drug use are available. To ensure a low threshold of the exchange program, no registration is necessary and high numbers of used needles and syringes can be exchanged.[14] This low threshold has most likely led to the sharp increase in distributed needles/syringes: from 100 000 per year in 1985 to approximately 1 000 000 per year in 1990, 1991, and 1992 (S. van Lieshout, personal communication).

The low-threshold methadone programs, operated by the Drug Department of the Municipal Health Service, are focused on stabilizing drug use and contacting drug users so they can receive appropriate social and medical care.[15] The illicit injection and other use of opiates or other drugs is tolerated. Although they are not primarily aimed at preventing HIV infection, these programs may contribute to AIDS prevention by lowering the frequency of injecting (methadone being a substitute for heroin) and increasing the proportion of drug users receiving educational information on AIDS.

Study Design

In December 1985, an open and ongoing cohort study among drug users was started in Amsterdam.[1,2,5,6,9] The participants for this study are recruited from methadone posts, from a sexually transmitted disease clinic for addicted prostitutes, and, to a lesser extent, by word of mouth. Participation in the study is voluntary, and informed consent is obtained. In the first 3 years, participants were seen at eight different locations. Since 1989, they have been seen at one central location, except for the addicted prostitutes, who are still interviewed at the sexually transmitted disease clinic. At intake, participants are given standardized questionnaires, which are administered by specially trained nurses; questions regarding current behavior refer to the previous 6 months.

Between December 1, 1985, and November 30, 1992, a total of 973 drug users entered this cohort study. For the present study, 616 of these users who had reported injecting during the 6 months preceding intake were selected. The only data used to determine trends in risk behavior were collected at intake visits. A large individual risk reduction has already been reported.[9] However, the validity of self-reported behavioral changes during follow-up is questionable when one considers the high and stable incidence of injecting related viral infections during follow-up.[16] In addition, injecting drug users who visited more than once appear to differ from single visitors, which might have led to a selection bias.

Trends in high-risk behaviors were determined over five periods of intake visits (1986 [n = 182], 1987 [n = 137], 1988 [n = 106], 1989/90 [n = 125], and 1991/92 [n = 66]). The smaller number of injecting drug users in the last periods is owing to a temporary cessation of recruitment of new participants between September 1990 and August 1991. The variables were divided into four sets. The first set consists of the three outcome variables that reflect current behavior (i.e., behavior measured over the 6 months preceding intake): borrowing needles or syringes already used by somebody else (yes, no), lending used needles/syringes to others (yes, no), and reusing one's own needles/syringes (mainly, not mainly). These variables do not include "frontloading" (i.e., injecting some drug solution into the front of another syringe of which the needle has been taken off in order to honestly divide drugs).[17] This behavior seems to be not very prevalent in Amsterdam.

Trends in risk behavior over time might be fully explained by a selection bias of participants over time; injecting drug users with certain characteristics that might be related to injecting risk behavior could have selectively entered the study over time. Therefore, trends in risk behavior were multivariately adjusted for differences in general characteristics (set 2) and current behavior variables (set 3), shown in Table 1. Sets 2 and 3 are distinguished because adjustment for current behavior might lead more easily to overmatching than adjustment for general characteristics; variables like age and gender cannot be influenced by interventions whereas variables for current behavior can. For example, if it is assumed that both borrowing and cocaine injecting decline in time (owing to intervention) and that cocaine injectors borrow more often than heroin injectors, adjusting the effect of year of intake visit on borrowing for frequency of cocaine injecting would lead to overmatching.

In 1989, the coding categories of the general characteristics of time living in Amsterdam, duration of injecting, and frequency of borrowing since 1980 were changed from broad categories to exact number of years or times. Only for frequency of borrowing did this result in more missing values (before 1989, 1% were missing; from 1989 on, 16% were missing.) Subjects with missing values on this variable were included in the multivariate analyses within a separate category, "missing." On all other variables, less than 1% of subjects had missing values. The current behavior variables were not subject to important changes.

The intervention variables, which may have a protective effect on high-risk behavior, form the fourth set. These variables include being previously tested for HIV (never, tested HIV positive, tested HIV negative), currently receiving methadone daily via methadone programs (yes, no), and currently obtaining new needles/syringes via exchange programs (0%, 1% to 99%, 100%).

In general, all testing was done two-tailed, and a P value of .05 was the criterion of significance. Statistical significance of trends was univariately analyzed using chi-square trend tests for categorical variables and Spearman's rank correlation tests for continuous variables. Multivariately, logistic regression was used to adjust for differences between participants over time, to determine significant and independent predictors for the outcome variables, and to investigate interactions between important variables.[18] Significance was based on the likelihood ratio statistic. The fit of the models was evaluated by calculating variable specific delta betas; no observations showed a disproportionally large influence on the odds ratios. The fit was also assessed using the Pearson goodness-of-fit test; this test was never significant. For all analyses, SPSS 4.0 was used.[19]

Results

Of the 616 injecting drug users who had injected during the 6 months preceding intake and who entered our study between 1986 and 1992, 57% were men and 43% women, with mean ages of 31.2 (SD = 5.8) and 27.5 (SD = 5.7) years, respectively. Of these current injectors at intake, 57% had their last injection 1 day ago or less, 18% had injected 2 to 7 days ago, 13% had injected 1 to 4 weeks ago, and 13% had injected 1 to 6 months ago. Sixty percent had currently injected mainly speedballs (a mixture of heroin and cocaine), and 24% had injected mainly heroin.

Unadjusted and Adjusted Trends in High-Risk Behavior

The three outcome variables showed a strong and highly significant decline per intake period (Table 1). From 1986 through 1991/92, borrowing needles/syringes decreased from 51% to 20%; lending, from 46% to 10%; and reusing, from 63% to 39% (all $P < .0001$). The concept of role separation is of epidemiological importance here since the incidence pattern of HIV depends on the proportion of injecting drug users who only borrow or lend and on the porportion of those who do both.[20] In 1986, 36% reported neither borrowing nor lending, 14% reported only lending, 18% reported only borrowing, and 32% reported both risk behaviors. In 1991/92, these figures were 77%, 3%, 13%, and 7%, respectively.

Table 1 also shows trends in general characteristics and current behavior variables per intake period. Per intake period, both the mean age and the proportion of men significantly increased, whereas the frequency of borrowing since 1980; the proportion of injecting drug users currently prostituting; and the proportions of users using amphetamines, barbiturates, and tranquilizers orally all show decreases.

Unadjusted and adjusted trends in the outcome variables were calculated by entering the period of intake visit continuously into logistic regression models in three ways: (a) unadjusted (bivariately), (b) adjusted for general characteristics (set 2), and (c) additionally adjusted for current behavior variables (sets 2 and 3). It appears that the odds ratios reflecting the decrease in borrowing, lending, and reusing needles per period of intake visit hardly changed after adjustment (model a compared with models b and c, Table 2). Therefore, the decrease in high-risk behavior was probably not caused by selective participation over time.

TABLE 1—Trends in Outcome Variables, General Characteristics, and Current Behavior Variables, among 616 Intake Visitors Who Had Injected Drugs during the Previous 6 Months

Evaluation of Specific Interventions

The variables concerned with potentially protective interventions also showed trends. Participants recruited later in time had been previously tested for HIV more often, received daily methadone less often, and obtained a higher proportion of new needles via exchange programs (all $P < .0001$, Table 3). The decrease in those receiving methadone is owing to a selective recruitment of participants at the methadone posts early in time. It may be that the decrease in risk behavior is related to these trends in intervention variables; indeed, in bivariate logistic regression analyses (unadjusted), injecting drug users who obtained all needles via exchange programs and those who had previously been tested for HIV (especially those whose test results were HIV positive) reported less high-risk behavior: they borrowed, lended, and reused needles significantly less often (Table 4). Receiving daily methadone was not strongly associated with either outcome.

For each outcome, a multivariate logistic regression model was constructed to determine independent predictors among the intervention variables and year of in-

[a]Reported over the 6 months preceding intake.

take visit, adjusted for general characteristics. (Additionally adjusting for current behavior variables yielded very similar results.) With regard to the outcomes of borrowing and lending, comparable results were found (Table 4). The likelihood of borrowing and lending decreased with a later period of intake visit and with having been previously tested for HIV, both variables bearing a stronger relation to lending than to borrowing. Multivariately adjusted, the relations between pbx-exchanging and the outcomes of borrowing and lending were weaker than they were unadjusted and were nc longer significant. Further analyses revealed that these relations weakened because of adjustment for the variable period of intake visit only.

Different results were obtained with regard to the outcome of reusing needles/syringes. Independent and significant predictors were having received an HIV-positive test result and exchanging needles/syringes frequently. However, the effect of period of intake visit was much weaker and no longer significant; this is probably explained by the increasing proportion of injecting drug users who frequently exchange over time.

Both the outcome variables and the intervention variables show statistically significant trends per intake period. It appears that these variables are also significantly interrelated except for the associations between receiving daily methadone and the three outcome variables or exchanging (Table 5). Therefore, severe problems of multicollinearity arise. For instance, adjusting the relationship between exchanging and borrowing or lending for period of intake visit might produce overmatching; however, one should adjust for calendar time to control for the potential presence of other (secular) trends (e.g., other preventive measures taken or a general spread of knowledge of safe injection methods).

To gain more insight into the mechanisms of the observed risk reduction, trends were compared in risk behavior among injecting drug users who did and did not receive daily methadone and who obtained syringes 100% and less than 100% via exchange. It appears that the proportion of users who reported current borrowing and lending decreased over time in all subgroups. Whether the magnitude of trends differed between the subgroups was then formally tested by evaluating if first-order interaction terms (i.e., between exchanging or receiving methadone and period of intake visit) could significantly improve a logistic regression model also containing the main effects. None of these interaction terms could do so (likelihood ratio test: $P > .11$).

Injecting drug users who obtained 100% of new needles/syringes via exchanging reported as early as 1986 that they were reusing their needles less often than those users who were exchanging them less. The relationship between reusing and exchanging became even stronger in time. This difference in the magnitude of trends (i.e., in subgroups based on strata of exchanging) was statistically significant (likelihood ratio test: $P = .04$). In 1986, injecting drug users who received daily methadone treatments also reported reusing needles less often than those who received methadone irregularly or not at all. However, the relation between reusing and receiving methadone disappeared in 1991/92. This difference in magnitude of trends was of marginal statistical significance (likelihood ratio test: $P = .08$).

Discussion

Among intake visitors in our cohort study of injecting drug users in Amsterdam, a substantial and continuous risk reduction occurred between 1986 and 1992. The proportion reporting current borrowing declined from 51% to 20%; lending from 46% to 10%; and reusing, from 63% to 39% (all $P < .0001$). However, there were some potential sources of bias in these trends.

First, participants showing a high level of risk behavior may have been selectively recruited earlier in time in our study. Therefore, we adjusted these trends multivariately for differences in eight general characteristics; the same decline in risk behavior was found. A possible drawback to this method may have been that injecting drug users differed in characteristics for which no information was available. However, even after addi-

tionally adjusting for nine current behavior variables, which theoretically could lead to overmatching, we found the same magnitude of decline in borrowing, lending, and reusing needles.

Second, we selected only drug users who had injected in the preceding 6 months. Assuming that, under the influence of the HIV epidemic, drug users initiate injection less often or are more likely to cease injecting, the decline in risk behavior among all drug users in Amsterdam would be underestimated.

Third, the prevalence of borrowing and lending may be underestimated owing to memory loss and the deliberate giving of socially desirable answers. However, underreporting would have had to increase systematically in time to explain the decrease in risk behavior. When we adjusted for having been tested for HIV and for participation in methadone and needle exchange programs—assuming that these interventions are markers for social desirability because they reflect more knowledge of risky behavior—the decline in borrowing and lending was still statistically significant. However, one can never rule out this type of bias since the norms against sharing in the entire injecting drug culture may have been strengthened.

Finally, the outcomes of borrowing and lending are only roughly measured. For example, it is likely that injecting drug users who borrowed injecting equipment that had already been used borrowed less often in the previous 6 months, borrowed less often from those testing HIV positive (e.g., they borrowed only from their HIV-negative steady partner), or adequately cleaned the needles and syringes more often. Given such changes, the decline in risk behavior would be underestimated.

The overall direction of these potential sources of bias is unknown. However, the observed risk reduction is in accordance with the stable HIV prevalence in Amsterdam and the decline in HIV incidence in our cohort.[5] We want to stress that, in 1992, 20% of injecting drug users still reported current borrowing and that the HIV incidence within our cohort was estimated to be 3 per 100 person-years. This indicates the need to improve the AIDS prevention campaign among injecting drug users in Amsterdam.

In the present study, we tried to evaluate the effects of three interventions on injecting risk behavior. Because of two general methodological problems, however, our results should be interpreted with caution. First, secular trends may be present. For instance, before AIDS prevention measures had been established in Amsterdam, it was already public knowledge that HIV could be transmitted parenterally. In addition, shortly after the start of specific programs for drug users, a national large-scale media campaign was executed in the Netherlands. Therefore, causality is difficult to prove. However, by multivariately adjusting the relationships between high-risk behavior and the intervention variables for year of intake period, we have (in part) adjusted for such secular trends. Second, in the present cross-sectional study, cause and effect cannot be distinguished. In Amsterdam, both HIV testing/counseling and attending exchange programs are voluntary. Thus, injecting drug users who were strongly motivated to reduce risk behavior or had already reduced it might have been attracted to these two interventions. On the other hand, the prevention programs can provide the means by which persons who are trying to avoid risk are in fact able to do so.

Despite these potential drawbacks, we found indications that voluntary HIV antibody testing/counseling reduces high-risk behavior. This intervention was related to all three outcomes (borrowing, lending, and reusing), independent of year of intake visit (secular trends) and other potential confounders. HIV testing is very strongly related to lending; almost none of the previously tested injecting drug users lent equipment to others. Injecting drug users who knew themselves to be HIV positive reported the lowest levels of risk behavior. However, being tested and found HIV negative does not seem to give false feelings of safety; these users were less likely to borrow than those who were never tested. In a review (1991), it was concluded that, "to date, the studies among injecting drug users do not provide compelling evidence for an effect of counseling and testing on either drug or sexual risk reduction."[11] In a clinical trial no protective effect was found.[21] Other recent studies, however, indicate beneficial effects.[22–26]

One important goal of the exchange programs is to promote the single use of needles and syringes, which is beneficial for hygienic reasons in general (e.g., to prevent bacterial and fungal infections). Beyond that, such behavior is expected to prevent HIV infection because habitual single-needle users will better organize injecting drug use, will less easily interchange injection equipment by accident, and will be more reluctant to borrow needles used by somebody else. Indeed, single-needle users reported less borrowing. The results of the present study suggest that the decrease in reusing equipment was caused by the increase in exchanging equipment. There was not only a strong but also a dose-effect relationship between exchanging and reusing needles, which was independent of year of intake visit (secular trends) and other potential confounders. Furthermore, a decline in reusing needles was only found among injecting drug users who exclusively exchanged needles. As for how attending exchange programs affected borrowing and lending, the results are difficult to interpret owing to multicollinearity (see Results).

No relation was found between receiving daily methadone and either outcome. However, because of methadone programs, drug users may have stopped drug injection. This might have led to a selection bias since participants eligible for the present study were required to have been currently injecting. Another complicating factor is that, owing to the low threshold of the programs, it is relatively easy to leave and reenter the programs. As a result, almost all injecting drug users in the present study received methadone after information on HIV became available at these programs. In any case, because in 1991 70% of the estimated 6500 drug users in Amsterdam received methadone,[27] low threshold programs are able to reach the majority of drug users, to whom information on HIV could be provided and syringe exchange and HIV testing/counseling services[28] could be offered.

Surprisingly, in the multivariate analyses, the decline in borrowing and lending was independent of intervention and other variables, and we found that injecting drug users attending needle exchanges or methadone programs reduced their risk to the same extent as nonattenders. Even among injecting drug users who neither obtained new needles via the exchange nor received methadone regularly, a significant risk reduction was found (data not shown). Not only secular trends (as described above) but also "contamination of the control group" may be responsible for these findings: nonattenders had probably received information about safe injection practices from attenders, and because of the exchange programs, the availability of needles/syringes may have been increased overall. For instance, exchangers may have given new injection equipment away to others more easily. At present, exchanging may be seen as a convenient way to obtain injection equipment, which is not strongly related to a desire to reduce risk.[5,29]

These findings have important implications for studies previously performed within our cohort. The lack of convincing evidence that attending exchange programs or receiving methadone treatments has a beneficial effect on the HIV prevalence, HIV incidence, or current borrowing[5,24,30] might be owing to the two factors mentioned above. Methodologically, evaluating specific prevention activities is very difficult. Even randomized intervention trials may be subject to secular trends and contamination of the control group. In the introduction to this paper, we mentioned limitations in the monitoring of HIV prevalence and incidence. Using the incidence of hepatitis B infection as a surrogate marker may give misleading results.[16]

However, a communitywide reduction in injecting risk behavior can be demonstrated by performing serial, cross-sectional studies using standardized questionnaires. In some serial, cross-sectional studies, a decline in injecting risk behavior was observed[31–34]; in others, no risk reduction was found.[13,23,35,36] Such differences between cities or regions may give clues to the relative effectiveness of prevention programs. However, apart from preventive measures, other differences between cities (e.g., drug use culture) complicate these comparisons.

In conclusion, a substantial risk reduction in injecting risk behavior has occurred since 1986 among injecting drug users in Amsterdam. Indications have been found that (1) voluntary HIV testing and counseling leads to less borrowing, lending, and reusing of injecting equipment; and (2) obtaining needles via exchange programs leads to less reusing of equipment. It appears that nonattenders of methadone and exchange programs have reduced borrowing and lending to the same extent as attenders. Therefore, evaluating specific measures methodologically is difficult. However, the combination of various measures in Amsterdam is probably responsible for the observed decrease in injecting risk behavior. □

The Provision and Use of Mental Health Services in Nursing Homes: Results from the National Medical Expenditure Survey

Michael A. Smyer, PhD, Dennis G. Shea, PhD, and Andrea Streit, MHA

ABSTRACT

Data from the Institutional Population Component of the National Medical Expenditure Survey were used to provide national estimates of annual mental health service provision and use in nursing homes. In addition, the relationship between service provision and setting characteristics such as ownership, size, Medicaid certification, and chain status was examined. Although more than three quarters of residents with a mental disorder resided at a nursing home that provided counseling services, fewer than one fifth actually received any mental health services within the year. (*Am J Public Health.* 1994;84:284–287)

Introduction

Mental health services in nursing homes are in transition. The Nursing Home Reform Act of 1987 (Public Law 100-203), part of the Omnibus Budget Reconciliation Act of 1987, mandates screening and services for mentally ill elderly persons who are seeking admission to nursing homes. Even as the legislation is being implemented, estimates are needed to provide a benchmark for progress in service provision. Recent estimates of monthly service provision[1] are based on the 1985 national nursing home survey. The purpose of this report is to provide estimates of annual service provision based on the most recent national data, before implementation of the Omnibus Budget Reconciliation Act of 1987.

This article uses data from the Institutional Population Component of the 1987 National Medical Expenditure Survey[2] to examine the relationship between the annual provision of mental health services in nursing homes and the need for and use of these services among nursing home residents. Because previous work suggests that nursing home ownership affects service provision,[3] the analysis distinguishes between for-profit, not-for-profit, government ownership, and other organizational characteristics.

Methods

Detailed information regarding the methodology for the Institutional Population Component of the 1987 National Medical Expenditure Survey is provided elsewhere.[4,5] This study examined only the resident sample obtained on January 1, 1987, which is a cross-sectional sample more likely to represent a longer staying and hence slightly more ill group.[6] The sample group of facilities analyzed here excluded those for mentally retarded persons because the focus is on the provision of mental health services in nursing homes. This sample also excluded facilities that were part of retirement centers or

FIGURE 1—The provision of counseling or psychotherapy by nursing homes.

hospitals because they are unrepresentative in terms of staff and clients.[7,8] Finally, facilities for whom ownership could not be determined were excluded. The resident sample excluded all persons who were reported to be comatose. Thus, our estimates may differ slightly from those reported elsewhere.[4]

Results

The results depict the provision of mental health services and residents' use of services. Figure 1 shows the percentage of nursing homes providing counseling or psychotherapy and the proportions of contract versus other arrangements both for the total sample and according to ownership category. As can be seen, slightly fewer than 60% of the nation's nursing homes, as estimated from the National Medical Expenditure Survey sampling frame, provided some counseling or psychotherapy service, with a plurality of homes (26.5%) providing services via contract with an outside therapist. There were clear differences according to ownership category; government facilities were most likely to provide counseling (82.7%).

Table 1 reports on nursing homes' provision of mental health services. Larger nursing homes were more likely to provide some counseling services, although the percentage of nursing homes providing counseling services among nursing homes with 150 or more beds actually was lower than it was among nursing homes with 100 to 149 beds.

Table 2 shows the types of personnel providing mental health services in nursing homes by ownership category, bed capacity, Medicaid skilled nursing facility certification, and chain status. More than

a quarter of the facilities reported that counseling was provided by a psychiatrist. The second most frequently cited provider was other mental health professionals, a category generally considered to represent workers with a bachelor's degree of some type. In general, government facilities were the most frequent users of psychiatrists and psychologists, whereas for-profit facilities were the most frequent users of "other mental health workers."

The provision of counseling or psychotherapy also clearly differed according to bed capacity, Medicaid certification, and chain status. Smaller facilities tended to rely more heavily on psychiatric social workers, although nearly half of the facilities reporting the provision of counseling reported of the use of a psychiatrist.

Table 3 indicates the number and percentage of nursing home residents who received mental health treatment by diagnostic categories and facility characteristics.

Seventy-five percent of the 835 000 nursing home residents with a mental disorder resided at a facility that provided some form of counseling or psychotherapy (data not shown). However, only 19% of these residents were reported to have received treatment. The rates of treatment were low in all types of facilities, although rates in not-for-profit and government facilities were slightly higher than those in for-profit facilities.

A similar pattern emerged when the experience of nursing home residents with specific mental disorders was examined. Roughly 70% of the residents with dementia only lived in a facility that provided counseling. However, only 5% to 12% received treatment, with those in governmental facilities being more than twice as likely to receive services than those in for-profit settings.

Discussion

This article summarizes the most current national data on the provision and use of mental health services in nursing homes. Three findings from the study are most salient. First, although more than three quarters of the residents with a mental disorder resided at a nursing home that provided mental health services, fewer than one fifth of such residents actually received any mental health services from the nursing homes at any time during the year, according to a very lenient definition of service receipt. In contrast, recent estimates suggest that fewer than 5% of nursing home residents receive mental health services within a month.[1]

Second, these data suggest that the types of personnel used to provide counseling and psychotherapeutic services vary by facility ownership and facility size. Not-for-profit facilities tend to rely on psychiatrists, psychologists, and social workers, whereas government facilities employ the highest percentage of psychiatrists. For-profit facilities tend to use more providers with little advanced training in mental health care. Smaller facilities rely more heavily on psychiatric social workers.

Third, the data are consistent with earlier reports of a substantial level of unmet need for mental health care within the nursing home setting.[1,9] Almost 65% of persons with mental health problems uncomplicated by dementia received no treatment while residing in a nursing home.

Two limitations of this study should be noted. First, these data were collected before the implementation of the Nursing Home Reform Act of 1987, with its emphasis on the provision of active treatment for mentally ill nursing home residents. It may be that higher rates of treatment will be revealed in the next National Medical Expenditures Survey, after implementation of the Omnibus Budget Reconciliation Act of 1987. At the very least, these data provide a benchmark for assessing the impact of the Omnibus Budget Reconciliation Act of 1987, as do earlier estimates.[1]

Second, there are reasonable concerns regarding the validity of the psychiatric diagnoses in the National Medical Expenditures Survey data. However, more than 90% of the staff-reported psychiatric diagnoses were confirmed by diagnoses in the residents' medical records. Thus, the validity of the findings is ensured to the extent that the medical records are accurate. However, there is a fiscal incentive for nursing homes to underdiagnose mental illness among their residents.[10,11] Thus, the data presented here may underestimate the rates of mental disorders and the effective provision of mental health services in nursing homes. □

Psychotic Inpatients' Social Class and Their First Admission to State or Private Psychiatric Baltimore Hospitals

Carles Muntaner, MD, PhD, Paula Wolyniec, MA, John McGrath, MA, and Ann E. Pulver, ScD

ABSTRACT

Social class differences were investigated among patients admitted to public and private psychiatric hospitals. Participants included first admission White psychotic men admitted to Baltimore metropolitan area hospitals between 1983 and 1989. After adjusting for age and diagnosis, patients with low levels of skills/credentials were found to be more likely than patients with higher levels to be admitted to state psychiatric hospitals. These findings underscore the persistence of social class as a determinant of differences in the use of psychiatric care. (*Am J Public Health.* 1994;84:287–289)

Introduction

The study of the social class of the severely mentally ill in relation to their use of mental health services has a long tradition in public mental health research.[1–5] Clearly, social class is one of the determinants of health care usage. Through its effect on income,[6] for example, social class might determine the availability of health insurance.[7] Additionally, past studies of mental health hospital admissions have shown that social class has an influence on the type of facility to which mental patients are admitted.[e.g.,2] These studies have focused primarily on the most severe forms of mental disorder (e.g., psychotic disorders, schizophrenia in particular), which require long periods of hospitalization.[8,9] The aim of the present research was to investigate whether, among White male psychotic patients, social class is associated with first admission to state or private hospitals in the Baltimore metropolitan area.

Methods

Private, state, and community general hospitals with psychiatric units or service departments in the Baltimore metropolitan area were contacted for recruitment of potential participants.[10] Five of six state hospitals (with capacities of 48, 54, 350, 367, and 480 beds) and two of three private hospitals (with capacities of 220 and 322 beds) agreed to allow their patients to participate. The single private hospital that was not approached serviced only women.

Among Baltimore area community general hospitals with psychiatric units, only half were included in the original design. Because it was felt that valid inferences about patients from such hospitals could not be made if only half the facilities participated, patients recruited from these facilities were excluded from the present

analyses. Furthermore, because the sample did not include the private women's hospital, the analysis was restricted to men.

Research participants were recruited through systematic screening of all White inpatients with psychotic symptoms or diagnoses who were aged 16 and over and were first admitted to Baltimore metropolitan state and private mental hospitals (described above) between 1983 and 1989.[10] (The study was originally funded to test genetic hypotheses regarding psychotic disorders among White patients.) Two hundred forty-eight of these admissions were male.

Prior to their release from the hospital, consenting patients were administered a modified version of the Diagnostic Interview Schedule[11] by a master's level clinical psychologist; details of the diagnostic procedures have been reported elsewhere.[10] Of the eligible White male first admission patients, 62% of those from state hospitals and 55% of those from private hospitals consented to participate in the study. (Response rates including women were similar: 60% and 53% for state and private mental hospitals, respectively.) This 7% difference between state and private patients was not statistically significant ($z = 1.13$, $P = .26$). For each type of facility, respondents were similar to nonrespondents with respect to diagnosis and education, but among private hospital inpatients, respondents were more likely to be younger (mean age = 28 years) than nonrespondents (mean age = 33 years).

Interview questions on family and employment history asked for the patient's last occupation prior to admission, the patient's usual occupation, and the occupation of the head of household when the patient was 16. Last occupation and occupation of head of household were used to classify patients. Students were classified according to their last occupation. The patient's last occupation showed a high correspondence to his usual occupation, as found in previous studies.[12]

Because continuous measures of education disregard the significance of credentials,[13] we used Wright's skills/credentials measure of social class.[14,15] This measure yields three social class categories (expert, marginal, and uncredentialed), based on the respondent's occupation and educational credentials.[14,15] Experts are defined as those holding jobs that require scarce skills, particularly credentialed skills, which are rare relative to their demand by the market (e.g., lawyers). Experts enjoy a credential rent: their wages are usually above the cost of reproduction of their training. They would be worse off with an equal endowment of society's pool of skills and credentials. Marginal and uncredentialed class members are defined as those holding jobs that only require common skills, particularly uncredentialed skills (e.g., construction laborers).[16]

We used logistic regression to estimate the association between social class and type of psychiatric hospital to which the patient was admitted. Age was considered a potential confounder because it has been found to be associated both with social class[16] and with type of hospital to which psychotic patients are admitted.[8] Psychiatric diagnosis was treated as a two-category variable: either schizophrenia or other cases with psychotic symptoms and diagnoses. Included in the latter category were patients with the following diagnoses: bipolar, schizoaffective, schizophreniform, and paranoid disorders; major depression; atypical, brief reactive psychoses; organic and substance-induced psychoses; and borderline or schizotypal personality disorders. Because there were no differences between marginal and uncredentialed classes in preliminary logistic regression analyses, the two categories were collapsed for the final analyses.

Results

The distributions of clinical and sociodemographic variables (diagnosis, age, family and patient's social class) are presented in Table 1. Patients diagnosed with schizophrenia were more likely to be admitted to state mental hospitals than pa-

TABLE 3—The Interaction Between Patient's Social Class and Type of Psychotic Disorder for White Male Psychotic Inpatients' First Admission to a State Mental Hospital, Baltimore Area, 1983 through 1989[a]

Independent Variables[b]	Adjusted OR	95% CI	P
Expert social class			
Other psychotic disorder[c]	1.00

[b]Adjusted for age and family social class.
[c]Reference category.

tients with other psychotic disorders. Similarly, patients located in the marginal and uncredentialed social classes were more likely to be admitted to state than to private hospitals; the reverse was observed for patients in the expert social class.

Table 2 presents the unadjusted estimates of the odds of being admitted to a state hospital versus a private hospital for each independent variable in the study. Patients diagnosed with schizophrenia were almost twice as likely to have been admitted to a state psychiatric hospital than to a private one, although the estimate was not statistically significant. Patients whose families were from marginal or uncredentialed social classes were 2.5 times as likely and patients whose own social class at the time of admission was marginal or uncredentialed were more than six times as likely to be admitted to a state psychiatric hospital.

Table 2 also summarizes the results from the multiple logistic regression model. Odds ratios were similar to bivariate analyses, with no evidence of confounding.

Table 3 presents the results from our exploratory analysis of the interaction between social class and diagnosis. Adding the interaction term for patients' social class and diagnosis improved the fit of the model ($\chi^2_{(1)} = 7.04$, $P < .01$). Patients in the marginal/uncredentialed social class who suffered from schizophrenia were comparatively more likely to be admitted to state mental hospitals than to private hospitals.

Discussion

Our results reveal that social class strongly influences location of the first admission to a psychiatric hospital among White male psychotic patients. Furthermore, the greater likelihood of White male schizophrenics being admitted to state mental hospitals than to private hospitals varies by social class.

It is important to note that our inferences are restricted to White male psychotic patients in the Baltimore metropolitan area for the period 1983 to 1989. The fact that our population consisted exclusively of White men allowed us to isolate the effect of social class. However, this precluded the study of possible interactions between class, gender, and race[17,18] in determining the site of first hospital admission. Further research on the effects of social class on mental health admissions might explore the role of additional dimensions such as organizational and productive assets[16] in predicting the type of facility to which patients are admitted. Studies including general hospitals, multiservice mental health organizations, and residential treatment centers[9] could reinforce our conclusion that social class remains an important determinant of location of care among psychotic patients. □

Psychiatric and Substance Abuse Disorders among Male Urban Jail Detainees

Linda A. Teplin, PhD

ABSTRACT

This paper presents prevalence rates by race/ethnicity and age for nine psychiatric and substance use disorders found in a random sample of 728 male jail detainees. Two thirds of the sample detainees had had a disorder other than antisocial personality during their lifetimes; half of these had had an episode within 2 weeks of the interview. More than 30% currently had either a severe mental disorder or a substance use disorder. Detainees with severe mental disorders or substance use disorders were most often in jail because they had committed nonviolent crimes. Policy implications of the results are discussed. (*Am J Public Health*. 1994;84:290–293)

Introduction

By law, mentally ill inmates must be treated for their disorders,[1-3] ideally receiving care comparable to what they would receive in the community.[4] Yet, as the Government Accounting Office notes, without better epidemiologic data, we cannot know how best to use the correctional system's scarce mental health resources.[5] The meteoric growth of jail populations[6] makes accurate epidemiologic data increasingly important.

Despite this need, there are few reliable data. Prevalence estimates of psychiatric disorders in jails vary widely[7-18] because of methodological inconsistencies across studies.[9] Moreover, no methodologically sound study has compared detainees' disorders with the crimes that precipitated their arrest. Such data are critical to planning treatment strategies for mentally ill jail detainees because the severity of the alleged offense determines, in part, the detainee's pretrial psychiatric treatment.[19,20]

This is the second of two epidemiologic papers analyzing data collected in 1983 and 1984 on 728 male jail detainees. The first paper was based on a subsample (n = 627) that could be compared with general population data from the Epidemiologic Catchment Area program; the analysis omitted 101 subjects who were Hispanic, younger than 18 years, or older than 60 years. Only schizophrenia and the major affective disorders were examined; the rates of these disorders among jail detainees were two to three times higher than general population rates.[9] In this paper prevalence rates are presented for the entire sample (n = 728) and by race/ethnicity (White, Black, and Hispanic) and age for nine current (within 2 weeks) and lifetime psychiatric disorders. The subject's arrest charge is also examined to see whether detainees with psychiatric disorders are in jail for more serious crimes than detainees with no disorder.

Methods

The subjects were a randomly selected, stratified sample (approximately one half misdemeanants, one half felons) of 728 male detainees interviewed at intake at Cook County Department of Corrections in Chicago, Ill. Of 767 detainees approached, 35 (4.6%) refused to participate. Four other subjects were excluded: two "duplicate" subjects (they were rearrested and randomly selected again) and two others who appeared to be confabulating their responses. The final sample total was 728. The National Institute of Mental Health Diagnostic Interview Schedule, Version III, which was developed for the Epidemiologic Catchment Area program, was used.[21] Because the sample was stratified by charge, all reported parameter and variance estimates were weighted to reflect the jail's true misdemeanant-to-felon ratio (55.9% misdemeanants and 44.1% felons). All reported standard errors and tests of significance have been corrected for these design effects.[22] Additional methodological information is available in the previous paper.[9]

Results

Nearly two thirds of the sample currently had one of the disorders listed in Table 1, and nearly 35% had a current disorder other than antisocial personality disorder. Rates of substance use disorders were extremely high: 29.1% (current) and 61.3% (lifetime). In the total sample, the proportions with either a severe mental disorder or a substance use disorder were 30.7% (current) and 61.8% (lifetime). Many subjects had both. Note that substance use *disorder* is more serious than *use*. Not surprisingly, antisocial personality disorder affected nearly 50% of the sample. As in the Epidemiologic Catchment Area study,[23] the rate of cognitive

This paper was accepted September 30, 1993.

impairment found in the present study (2.0%) may have been inflated because of testing bias, so it was eliminated from the analysis. Given the legal mandate to treat currently ill detainees, the tables present only current disorders.

Table 2 shows the prevalence rates for three categories of race/ethnicity: White (non-Hispanic), Black (non-Hispanic), and Hispanic. Overall F tests were performed to see whether there were differences in prevalence rates among the three groups; *t* tests between groups were performed only when the overall F test was significant.[24] Table 2 shows some interesting racial/ethnic differences. For example, Whites had higher rates than Blacks for many disorders. Moreover, Hispanics had significantly higher rates than Blacks for schizophrenia and drug use disorder. Note that several large estimated differences in Table 2 are not significant, possibly because the small n's within categories cause standard errors to be quite large.

Table 3 presents the prevalence rates by age group. To test for age differences, an overall F test of significance was conducted; when differences were significant, F tests for nonlinearity were performed.[25] Again, for some age groups, the standard errors for the specific severe disorders are quite large relative to the estimated rates. Overall, the prevalence of many disorders increased with age.

Table 4 shows the bivariate relationship between current disorder (the unit of analysis) and the subject's most serious current charge: violent felony, nonviolent felony, violent misdemeanor, or nonviolent misdemeanor. Chi-square tests were used to compare the current charge distribution of each of the diagnostic groups with that of the control group, detainees with no disorders. Only one comparison was statistically significant: the drug use disorder group had fewer arrests for violent crimes (misdemeanors and felonies) than did detainees with no disorder ($P < .01$). These data were also analyzed with the subject as the unit of analysis; each subject was categorized by his most severe diagnosis. The results (available from author) were the same.

TABLE 1—Current and Lifetime Prevalence Rates of Disorders among Male Jail Detainees (n = 728)

	Current[a]			Lifetime		
	%	No.	SE	%	No.	SE
Any DIS disorder[b]	62.40	429	1.65	76.93	553	1.36
Any except antisocial personality	34.96	247	1.64	67.47	489	1.71
Any severe disorder (schizophrenia, manic episode, major depressive episode) or substance use disorder	30.70	220	1.67	61.83	447	1.77
Severe cognitive impairment[c]	2.00	14	0.25	...	...	...
Severe disorder (schizophrenia, manic episode, or major depressive episode)	6.12	45	0.85	8.94	66	1.01
Schizophrenia/schizophreniform disorder	2.98	21	0.72	3.82	26	0.91
Manic episode	1.18	9	0.32	2.17	17	0.38
Major depressive episode	3.42	26	0.56	5.09	39	0.66
Dysthymic disorder[d]	...	...	...	8.53	59	1.24
Substance use disorder (drug or alcohol)	29.11	206	1.70	61.25	443	1.78
Drug abuse/dependence	15.26	116	1.14	32.37	236	1.73
Alcohol abuse/dependence	19.09	129	1.68	51.11	367	1.85
Anxiety/somatoform disorder[e]	11.62	86	1.10	21.02	156	1.42
Antisocial personality disorder	48.40	344	1.86	49.21	351	1.85

Note. Disorders are counted as present only if the subject met the "severe" or "definite" criteria of the Diagnostic Interview Schedule (DIS).[21] Possible or moderate cases are considered as no disorder. Subjects may meet criteria for more than one disorder; therefore numbers may sum to more than the total sample. Cell counts are based on unweighted data. Reported percentages are based on data weighted to reflect the actual ratio of misdemeanants to felons in the jail population. For this reason, the reported count divided by the total n does not equal the reported percentage. Reported percentages represent parameter estimates. Data are missing as follows: any current DIS disorder, missing for 26 subjects; any current disorder except antisocial personality, missing for 26 subjects; any current severe disorder (schizophrenia or major affective disorders) or substance abuse disorder, missing for 23 subjects; current anxiety/somatoform disorder, missing for 3 subjects; current obsessive-compulsive disorder, missing for 1 subject; current alcohol abuse/dependence, missing for 23 subjects; current phobic disorder, missing for 2 subjects.

[a]Within 2 weeks of interview.

[b]This category includes only those DIS disorders specifically reported in this table. Egodystonic homosexuality, sexual dysfunction, tobacco abuse, anorexia nervosa, pathological gambling, and transsexualism are excluded.

[c]This diagnosis is determined by a brief mental status examination. See text for discussion of the diagnostic validity of this disorder.

[d]Recency of dysthymic disorder is not assessed by DIS version 3.

[e]This category includes the following disorders: phobia, panic disorder, obsessive-compulsive disorder, and somatization.

Discussion

More than 30% of the sample had a current severe mental disorder or substance use disorder, and nearly 62% had had one of these disorders at some time during their lifetime. As in the general population, alcoholism was extremely prevalent.[23,26,27] It is unlikely that the prevalence rates were inflated by the stresses of incarceration because subjects were interviewed during jail intake. DSM-III-R diagnoses require the exhibition of symptoms for a minimum of 2 weeks (longer for some disorders) or the existence of a prodromal phase.[28]

The finding that Whites had higher rates of some disorders than Blacks suggests a possible bias in the criminal justice process. Blacks have higher arrest rates than Whites[29] and, because they are poorer,[30] may have difficulty making bail. Blacks, mentally ill or not, are more likely to be jailed than Whites. In contrast, perhaps only the most dysfunctional Whites cannot make bail and are jailed before trial.

In contrast to the Epidemiologic Catchment Area study,[31] the present study found extremely high rates of schizophrenia (9.46%) among Hispanics. Further research is necessary to determine whether this finding is valid or whether it is due to testing bias in this jail population.[32,33]

Overall, the youngest age group (16 through 21 years) had the lowest prevalence rates for almost every disorder. Most likely, this is because the youngest subjects had not yet lived long enough to develop the disorders. They can be expected to develop additional disorders as they age.

The majority of disordered subjects were arrested for nonviolent crimes. Many of the severely ill detainees could have been diverted into the mental health system before arrest, before trial, or after release.[19] The diversion options depend, in part, on the severity of the charge. The American Bar Association recommends that mentally ill persons accused of minor crimes (misdemeanors) be diverted to mental health facilities, not arrested.[20]

TABLE 2—Prevalence of Current Disorders among Male Jail Detainees (n = 728), by Race/Ethnicity

	White, Non-Hispanic (n = 87)		Black, Non-Hispanic (n = 588)		Hispanic (n = 47)		Overall F Test	Significance and Direction of Pairwise *t* Tests[a]
	%	SE	%	SE	%	SE

Substance use disorder (drug or alcohol)	19.78	2.7	26.33	2.7	37.87	3.6	56.24	7.0	$P < .001$	NS
Drug abuse/dependence	10.98	1.8	13.15	1.7	22.08	2.7	21.41	5.0	$P < .01$	NS
Alcohol abuse/dependence	11.24	2.4	19.10	2.7	22.35	3.5	43.88	8.0	$P < .001$	NS
Anxiety/somatoform disorder	13.52	2.1	11.03	1.7	9.98	2.1	12.28	4.3	NS	
Antisocial personality disorder[b]	38.75	3.3	52.31	3.0	54.61	3.7	47.13	7.2	$P < .01$	$P < .05$

Note. Column n's are based on unweighted data. Reported percentages are based on data weighted to reflect the actual ratio of misdemeanants to felons in the jail population. For this reason, the reported count divided by total numbers does not equal the reported percentage. Reported percentages represent parameter estimates. Subjects may meet criteria for more than one disorder. See notes to Table 1 for details on missing data. NS = not significant at $P < .05$.

[a]The number of subjects aged 40+ years was too small to generate reliable rates for any of the severe disorders. F tests for these disorders were performed on the three reported cells.

[b]The Diagnostic Interview Schedule does not assess antisocial personality disorder for persons younger than 18 years. This age group has been omitted from this analysis. The n for the 18–21-year-old age group is 176.

Persons charged with felonies (even nonviolent felonies) must be adjudicated. Nevertheless, many detainees accused of nonviolent felonies could be treated outside the jail after their pretrial hearing if appropriate programs were available in the community.

If current rates of growth (15% to 20% per year) continue,[34–36] the national jail census will exceed 1 million by 1995. The number of jail detainees who will require treatment in the future—particularly for alcohol and drug abuse—is staggering. This is a critical public health problem because jails are not equipped to provide treatment.[12] Many jail detainees have multiple disorders, further complicating their treatment.[37,38]

The jail is a crucial point of intervention for persons whose psychiatric and substance abuse problems may lead them to commit minor offenses.[7,8] Crisis intervention treatment within the jail may help break the recidivistic cycle. Despite the legal mandate to treat disordered jail detainees,[1–3] few jails have adequate resources to treat either the mentally ill[19] or substance abusers.[39] Drug and alcohol treatment services are urgently needed. A recent nationwide survey of 1737 jails showed that only 28% provided *any* drug treatment services, and only 7% provided a comprehensive level of treatment.[39]

The median jail stay is only 3 days.[40] Thus, although treatment programs are needed, jails must also improve linkages with community mental health and substance abuse programs. Unfortunately, existing services are insufficient, especially for substance abuse.[41] Comprehensive drug and alcohol treatment services for jail detainees after release must become a priority. Diversion may also help reduce our burgeoning jail population.

Public health administrators must en-

TABLE 4—Male Jail Detainees (n = 726) with a Current Arrest Charge (%), by Current Diagnosis

Current Diagnosis	Felony		Misdemeanor		Chi-Square Test[a]
	Violent	Nonviolent	Violent	Nonviolent	
Schizophrenia/manic episode (n = 26)	15.4	46.2	3.8	34.6	NS
Major depressive episode (n = 26)	19.2	46.2	15.4	19.2	NS
Both drug and alcohol abuse/dependence (n = 32)	12.5	43.8	9.4	34.4	NS
Drug abuse/dependence (n = 116)	10.3	55.2	4.3	30.2	$P < .01$
Alcohol abuse/dependence (n = 128)	14.1	36.7	11.7	37.5	NS
No disorder (n = 504)	18.5	39.0	9.0	33.5	
Total	17.1	41.0	8.5	33.3	

Note. Row n's are based on unweighted data. Totals may not equal 100% because of rounding. Two subjects with cognitive impairment were excluded. Subjects may meet criteria for more than one disorder. NS = not significant at $P < .05$.

sure that jail treatment programs meet recently developed mental health standards.[42] Jails will then be in compliance with the courts, and jail detainees will receive the most effective and humane treatment possible within the correctional setting as well as after release. □

Enhancing the Self-Report of Alcohol Consumption in the Community: Two Questionnaire Formats

Abby C. King, PhD

ABSTRACT

Two questionnaire formats for assessing alcohol consumption in a community sample were compared. Subjects completed the Semi-Quantitative Food Frequency Questionnaire and a questionnaire specifically targeting alcohol use. Across all alcoholic beverages, subjects reported lower consumption on the alcohol questionnaire than on the food frequency questionnaire. The results suggest that food frequency questionnaires may provide a better means for enhancing self-report of alcohol use than questionnaires that target solely alcohol intake. (*Am J Public Health.* 1994;84:294–296)

Introduction

Assessment of alcohol consumption typically involves targeting alcohol use directly or obtaining alcohol data as part of a more general dietary assessment.[1–4] When a specific alcohol questionnaire is used, respondents may be more likely to attend to the questions, and a more accurate report may be obtained.[5] In contrast, embedding alcohol intake questions in a general diet questionnaire may neutralize the negative feelings toward alcohol reporting potentially evoked in some population segments[6,7] and/or increase the number of associated cues that can enhance recall.[8] Little is known about reporting issues for the moderate drinking levels that are of greater relevance for public health research.[9]

Direct comparisons of the above two questionnaire methods have been rare.[10] The purpose of this study was to determine whether embedding alcohol questions in a general diet questionnaire would lead to increased reporting of alcohol use among a community-based sample. A food frequency questionnaire was chosen since such questionnaires are currently one of the primary methods for measuring dietary intake in public health research.[11]

Methods

Subjects

Subjects originated from a sample of 357 men and women who agreed to participate in a study evaluating the effects of increases in community-based physical activity on health outcomes.[12] Residents of Sunnyvale, Calif, between 50 and 65 years old were recruited through a random-digit dialing community telephone survey and citywide promotion.[13]

Procedures

Prior to randomization, subjects underwent two evaluation sessions scheduled 3 days apart. All subjects completed a semiquantitative food frequency questionnaire. In addition, the final 237 subjects entering the study completed an alcohol consumption questionnaire. These 237 individuals constitute the sample of interest. The order in which each subject completed the two questionnaires (i.e., during session 1 or 2) was determined randomly.

Measures

Food frequency questionnaire. The Semi-Quantitative Food Frequency Questionnaire was used to measure dietary intake over the previous year.[14] This questionnaire has proven to be reproducible and valid across a variety of nutrients, including alcohol.[14,15] Among its advantages are ease of administration across large samples and specification of drink size for different types of alcoholic beverages.[14]

Alcohol consumption questionnaire. The alcohol consumption questionnaire was composed of the same questions as the food frequency questionnaire with respect to the frequency of beer, red wine, white wine, and liquor consumed over the past year.

Statistical Analysis

Two categories were defined for each questionnaire: nondrinkers (those choosing the "never or less than once monthly" category) and drinkers (those choosing any of the other eight alcohol use categories). The McNemar symmetry chi-square statistic for paired comparisons[16] was used to compare the frequencies obtained across the two questionnaires for each alcoholic beverage separately and for all types of alcoholic beverages combined. Cohen's kappa was applied to measure agreement across the two questionnaires.[16]

Subjects' alcohol responses were then grouped into four categories and compared across the two questionnaires.

This paper was accepted June 23, 1993.

The categories were nondrinker (never or less than one drink monthly), light drinker (one drink per week through one drink per month), moderate drinker (one drink per day through two drinks per week), and heavy drinker (two drinks per day or more). These categories reflect the somewhat lower alcohol consumption rates typically reported by people in this older age group.[17]

Results

Descriptive data for the 237 subjects are shown in Table 1. Subjects were comparable on these variables to the larger study sample from which they were drawn, and they were similar to the northern California population from which they were recruited (Table 1).[12] The mean number of drinks per previous 2-week period reported by those indicating alcohol intake over the past year on the alcohol consumption questionnaire was similar to that of national samples in this age range.[18]

TABLE 1—Baseline Descriptive Statistics of Study Sample and a Representative Sample of the Target Community

	Study Sample		Community Sample[a]	
	Men	Women	Men	Women
No.	135	102	765	1109
Age, y (mean ± SD)	56.4 ± 4.1	57.0 ± 4.3	56.8 ± 4.4	56.9 ± 4.5
Education, y (mean ± SD)	15.8 ± 2.5	14.1 ± 2.4	15.2 ± 3.0	13.7 ± 2.7
Caucasian, %	89.1	88.7	88.4	92.2
Body mass index, kg/m^2 (mean ± SD)	27.2 ± 4.2	26.1 ± 5.1	26.0 ± 3.6	25.0 ± 3.6
Cigarette smokers, %	17.3	23.5	18.5	25.6
Alcohol intake over previous 2-week period, No. of drinks[b] (mean ± SD)	10.5 ± 8.6	6.3 ± 5.3	12.8 ± 16.4	6.5 ± 10.9

Note. There were no statistically significant differences between the two groups on the variables evaluated.
[a]Based on a random-digit dialing telephone survey of people 50–65 years of age residing in Sunnyvale, Calif, during the period in which the clinical trial recruitment was initiated.
[b]For subjects reporting some alcohol intake during the past year on the alcohol consumption questionnaire (the study sample included 83 women and 120 men; the community sample included 914 women and 658 men).

Classification of Drinkers and Nondrinkers on the Two Questionnaires

The amount of interquestionnaire agreement for the drinking/nondrinking classification is shown in Table 2. For all four types of alcoholic beverage, the alcohol consumption questionnaire resulted in significantly fewer individuals classified as drinkers than did the food frequency questionnaire (Ps < .05). Cohen's kappa ranged from .48 (white wine) to .70 (liquor), signifying fair to good agreement between the two questionnaires.[16] Comparable analyses conducted separately for each sex led to similar results.

When a nondrinker was defined as an individual having no drinks or less than one drink per month across all types of alcoholic beverages and a drinker was defined as someone having one drink or more per month, significant discrepancies between the two questionnaires continued ($P < .002$; $\kappa = .45$). While 83.5% of subjects were identified as drinkers on both questionnaires, there was discordance between the two questionnaires for 11% of the sample, with the alcohol consumption questionnaire identifying lower numbers of drinkers than the food frequency questionnaire.

Analyses indicated similar reporting patterns regardless of whether the food frequency questionnaire was completed on day 1 or day 2.

Relative Frequency of Alcohol Intake

In addition to identifying fewer drinkers relative to the food frequency questionnaire, the alcohol consumption questionnaire generally resulted in a lower reported frequency of intake among drinkers across all three drinking frequency categories (light, moderate, and heavy) (see Table 3).

Discussion

Although it was completed within 3 days of the food frequency questionnaire and used identically worded items and time frame, the alcohol consumption questionnaire consistently resulted in the identification of a smaller percentage of drinkers and a lower reported frequency of alcohol intake. Although clearly not representative of the US population as a whole in this age group, the study sample did provide a good representation of the subjects in the age range of interest residing in the target community, which was

The Frequency and Nature of Alcohol and Tobacco Advertising in Televised Sports, 1990 through 1992

ABSTRACT

This study examines the frequency and nature of alcohol and tobacco advertising in a random sample of 166 televised sports events representing 443.7 hours of network programming broadcast from fall 1990 through summer 1992. More commercials appear for alcohol products than for any other beverage. Beer commercials predominate and include images at odds with recommendations from former Surgeon General Koop. The audience is also exposed to alcohol and tobacco advertising through the appearances of stadium signs, other on-site promotions, and verbal or visual brief product sponsorships. Moderation messages and public service announcements are rare. (*Am J Public Health.* 1994;84:297–299)

Patricia A. Madden, MPH, and Joel W. Grube, PhD

Introduction

Alcohol and tobacco advertising is of interest to public health professionals because of its potential effects on consumers. In particular, concern has been expressed that this advertising may influence children.[1–3] Consistent with such concerns, most research has found small but significant correlations between exposure to alcohol and tobacco advertising and youth drinking and smoking attitudes and behavior.[1,4–8] Research has also shown that children's exposure to televised beer advertisements occurs primarily through sports programming.[8] Although tobacco commercials were banned from electronic media in 1971, nonstandard tobacco advertising (e.g., stadium signs and other visual and verbal references) broadcast to the television audience provides a vehicle for the tobacco industry to circumvent the federal ban. The present study documents the frequency and nature of alcohol and tobacco advertising in television sports programming. Advertisers' use of celebrity endorsers and images of activities that can be dangerous when paired with alcohol use is also examined.

Methods

Sample

A random sample of college and major professional sports events (football, baseball, and basketball) broadcast on network television from fall 1990 through summer 1992 was videotaped. All sampled events were broadcast on weekends before 5 PM, with the exception of "Monday Night Football." Beginning in summer 1991, the sample was expanded to include other sports such as golf, auto racing, bicycling, and Olympic coverage. Overall, 35 college sports events, 66 major professional sports events, and 65 other sports events, representing 443.7 hours of broadcasting, were studied (see Table 1).

Measures

All standard and nonstandard advertisements were assessed. Nonstandard advertisements were categorized as (1) stadium signs, (2) other on-site promotions (physically or audibly present to fans at the event), or (3) brief product sponsorships (visible or audible to the television viewing audience only). Other on-site promotions included logotypes on the sides of racing cars and giant blow-up beer cans; the typical format for a brief product sponsorship was as follows: "This game is being brought to you by X company." Each sports event was divided into 1-minute intervals, and each interval was coded for the presence of each type of nonstandard advertising. All occurrences of moderation messages or warnings about improper use of alcohol imbedded within advertisements were recorded.

Two hundred eight unique or distinct beer commercials were identified within the sample of sports programming. These unique commercials were coded for the presence of (1) celebrity endorsers, (2) cars or driving, and (3) water activities. The water activities category included water sports (e.g., kayaking, jet skiing), as well as scenes with people in boats or near water (e.g., beach, lake, swimming pool).

Eighty-three percent of the sports events in our sample were viewed independently by two coders. Intraclass correlation coefficients[9] for the reported variables ranged from .91 to 1.0. When disagreements arose, the average of the two coders' judgments was taken as the final count for analysis.

[a]Major league football, baseball, and basketball.
[b]Auto racing, bicycling, bowling, diving, figure skating, golf, gymnastics, ice hockey, skiing, tennis, track and field, volleyball, yachting, and mixed event programs such as "Wide World of Sports" that include boxing, horse racing, and so forth.

vised sports programming. Six hundred eighty-five alcohol (beer, wine, wine cooler) commercials were broadcast in the 443.7 hours of sports programs. This figure represents more than three quarters (77%) of all beverage commercials. Nonalcoholic beer products accounted for 4% of all beverage commercials, while all other types of beverages combined (soft drinks, coffee, juice, etc.) accounted for 19%.

Table 2 compares the hourly rates of standard commercials for alcoholic beverages among types of sport programs. Just over 1.5 alcohol commercials, on average, were broadcast for each hour of sports programming. Beer commercials predominated wine and wine cooler commercials ($P < .05$ in both cases; Friedman test).

About 10% of the unique beer commercials were product oriented, simply showing images of the bottle and advertising the good taste and quality of the beer. Celebrity endorsers (often athletes or entertainers) appeared in 15% of the commercials. Approximately 16% contained images of cars or other motor vehicles, and 26% showed water activities. In all, 37% of the commercials contained either driving or water-related images.

Nonstandard advertising. Table 3 presents the hourly rate of appearances of stadium signs, other on-site promotions, and brief product sponsorships. Overall, such nonstandard advertising was common, occurring 3.3 times per hour. Stadium signs and brief product sponsorships were more prevalent in major professional sports events than in college or other sports events ($P < .05$; analysis of variance of ranks). Other on-site promotions were found predominantly in the "other sports" category (e.g., boxing and auto racing with alcohol insignia on the clothing of the boxers and drivers as well as advertising on the floor of the boxing ring and on the cars).

Nonalcoholic beer advertisements. Thirty-nine broadcasts of nonalcoholic beer commercials were found. Stadium signs, other on-site promotions, and brief product sponsorships for nonalcoholic beer appeared as well, primarily in golf tournaments.

Moderation messages. Of 685 broadcasts of alcohol commercials, only 3 contained moderation messages. In addition, 10 of the brief product sponsorships (about 3%) contained moderation messages (Budweiser's "Know when to say when" and "Friends know when to say when" slogans). Two segments produced in a "public service announcement" manner by a beer company addressed underage drinking and drinking and driving. The sponsor's name was featured, but no product was visible, and the messages focused exclusively on prevention.

Public service announcements. Ten broadcasts of alcohol-related public service announcements were found. These segments addressed drinking and driving, alcohol-free prom/graduation nights, and teenagers' negative behavior after intoxication.

Tobacco

The primary way in which tobacco is advertised in sports programming is through appearances of stadium signs (see Table 3). Major professional sports programming involves the highest frequency of appearances of signs per hour, followed by other sports programming ($P < .05$). Most brief product sponsorships (76%) and other on-site promotions (80%) appeared in the four auto racing events in the sample; such nonstandard advertisements

appeared in 219 of the 467 one-minute intervals (47%) during the broadcast of the four races. Overall, nonstandard tobacco advertising occurred 1.5 times per hour. No antismoking public service announcements were broadcast.

Discussion

This study provides a basis for monitoring trends in the frequency and nature of alcohol and tobacco advertising in televised sports programming. Results show that alcohol advertising is common. Beer commercials predominate and often feature celebrity endorsers and activities such as driving or being near water. These images or themes are at odds with former Surgeon General Koop's 1989 recommendations that alcohol advertising not portray activities that are dangerous when combined with drinking and that such advertising avoid celebrity endorsers, especially those who appeal to young people.[10] Viewers are also exposed to alcohol advertising via stadium signs, other on-site promotions, and brief product sponsorships. Moderation messages and public service announcements relating to alcohol are rarely broadcast. Thus, sport viewers receive primarily positive messages about drinking.

An outright ban of all types of alcohol advertising on television has been suggested. However, some public health researchers have cautioned against making the same mistake with alcohol as may have been made with tobacco.[11] Cigarette consumption actually increased after the 1971 ban, perhaps because of the discontinuation of equal time antismoking spots; the freeing of large sums of money, which the tobacco industry used for diversification; and the locking out of new competition through the elimination of access to the national audience.[12]

Short of an advertising ban, various restrictions have been suggested. Limiting alcohol advertising during times children are most likely to view (weekend mornings, early prime time, and times during which sports programming is broadcast) is one option.[8] Prohibiting images of automobiles, race tracks, speed boats, and other references to driving and speed in alcohol commercials has been suggested.[10,13] Former Surgeon General Novello appealed to the tobacco and alcohol industries to stop using cartoons or other images that appeal to children. Counteradvertising, such as that currently targeting smoking in California, and health warnings in electronic alcohol advertising also have been suggested. Finally, the presence of nonstandard advertising for tobacco products indicates a need to reexamine the definition of advertising currently used in enforcing the cigarette advertising ban. Cigarette stadium signs, other on-site promotions, and brief product sponsorships certainly expose viewers to cigarette advertising. The fact that such promotions appear on television is at odds with the intent of the 1971 ban. □

The Illegal Sale of Cigarettes to US Minors: Estimates by State

ABSTRACT

Data available from recent national surveys on the cigarette consumption and purchasing practices of teenage smokers were used to generate state-specific estimates of the number of teenage smokers and cigarette sales to minors. In 1991, approximately 2.7 million teenage cigarette smokers consumed an average of 28.3 million cigarettes per day (516 million packs per year). An estimated 255 million packs of cigarettes were sold illegally to minors in 1991. To make cigarettes and other tobacco products less accessible to minors, policymakers should consider implementing various legislative and economic measures such as banning cigarette vending machines and raising tobacco excise taxes. Introduction

Cigarette smoking kills more than 400 000 Americans each year.[1] Most tobacco victims are over the age of 35[1]; however, the addiction that fosters tobacco use begins for a majority of smokers during adolescence.[2] In an effort to deter minors from initiating and sustaining tobacco use, most states have enacted laws that restrict the sale of tobacco to minors.[3] Despite the existence of these laws, evidence indicates that most teenage smokers buy their own cigarettes with little difficulty.[4–10]

In an effort to promote greater awareness of the problem of youth tobacco use and access, this study presents estimates of teenage smoking and the illegal sale of cigarettes to minors in each of the 50 states and the District of Columbia.

Methods and Materials

Data collected in the 1989 Teenage Attitudes and Practices Survey of 12- to 18-year-old youth, sponsored by the Centers for Disease Control, the National Cancer Institute, and the American Cancer Society, were used to generate state-specific estimates of the number of teenage smokers.[11] The survey is based on a representative national sample of 9965 young people. Since our main interest in this study was estimating the sale of cigarettes to teenagers, we restricted our definition of a smoker to anyone who reported having smoked in the last week. This definition provides a conservative estimate of teenage smoking but is more likely to capture those who regularly purchase their own cigarettes.[7–10]

Table 1 shows the age-specific prevalence estimates obtained from the Teenage Attitudes and Practices Survey. Teenagers who reported having smoked in the last week were asked to indicate the amount they smoked daily. Daily cigarette consumption among current smokers is also reported in Table 1.

Census figures from 1990 were used to estimate the number of teenagers in each age group by state. Multiplying the cigarette use prevalence figures shown in Table 1 by the number of teens in each age group yields an estimate of the number of smokers between the ages of 12 and 18 years in each state. Multiplying the average number of cigarettes consumed daily from Table 1 by the number of teenage smokers in each age group provides an estimate of the number of cigarettes consumed daily by teens in each state.

Data from a 1989 study on the cigarette purchasing habits of teenage smokers conducted by the National Automatic Merchandising Association[5] (a trade association for companies that sell cigarettes from vending machines) were used to estimate the percentage of cigarettes consumed by teens that represent sales to minors. In that study, the purchasing habits of 1015 teenage smokers interviewed in shopping malls in 20 US cities were assessed. Seventy-two percent of teenage smokers indicated that they obtain their cigarettes by purchasing them, while an additional 19% reported that they depend on friends to supply them. Since the friends of most teenagers are themselves minors, this study indicates that 91% (72% + 19%) of all cigarettes consumed by teens are sold to minors. These findings are consistent with results from other studies that have examined the cigarette purchasing habits of teenage smokers.[10,12]

State laws vary in regard to the minimum age for selling cigarettes to minors.[3] The estimated number of packs of cigarettes illegally sold to minors was calculated separately by state according to each state's minimum age law (see Table 2). Multiplying the number of packs of cigarettes consumed by teens by 0.91 provides an estimate of the number of packs sold illegally to minors each day. Sales and tax

[a]As of November 1, 1989.

data compiled by the Tobacco Institute[13] for 1991 were used to determine estimates of sales and tax revenue generated from the illegal sale of cigarettes to minors on a state-by-state basis.

Results

Table 2 shows the estimated number of smokers 12 to 18 years of age by state and the District of Columbia. Overall, we estimate that approximately 2.7 million teenagers smoked an average of 28.3 million cigarettes per day (516 million packs of cigarettes per year).

Table 2 also provides estimates of sales and tax revenue derived from the illegal sale of cigarettes to minors. In 1991, four states, Louisiana, Missouri, Montana, and New Mexico, did not have tobacco age sale restriction laws (since 1991, Louisiana and Missouri have passed laws banning the sale of tobacco to those under the age of 18) and thus did not contribute to the overall estimate for illegal sales to minors. Taking into account differences in state laws regarding minimum age restrictions for selling cigarettes to minors, we estimate that, in 1991, 255 million packs of cigarettes were sold illegally to minors.

[a]As of July 1, 1991.

Discussion

The results of this analysis show that US teenagers spent $962 million on cigarettes in 1991. Our estimate of cigarette expenditures by teens is probably conservative since we did not consider tobacco use by teenagers who smoke less fre-

quently than once per week. However, even using this conservative approach to computing cigarette expenditures by teenagers, we estimate that, in 1991, the cigarette industry derived approximately $190 million in profit from sales to minors ($94.8 million from illegal sales). Of course, the profit derived from cigarette sales to teenagers is tiny in comparison with the profits obtained from sales to adults. The financial incentive for the tobacco industry to persuade teenagers to smoke is not the short-term profit gained from selling cigarettes to them but the expected stream of profit to be gained over a smoker's lifetime.

The federal government and state governments also benefit financially from tobacco sales to teenagers. In 1991, we estimate that combined federal and state taxes collected on the sale of cigarettes to teens between the ages of 12 and 18 years exceeded $240 million ($122 million derived from illegal sales to minors). The federal and state governments should consider earmarking tax revenues collected from the illegal sale of cigarettes to minors to programs enforcing tobacco age restriction laws.

The public supports stronger limits on children's access to and use of tobacco products.[14–16] Evidence from several studies[9,17,18] indicates that when tobacco age restriction laws are enforced, tobacco sales to minors can be sharply reduced. Two recent studies[19,20] also provide evidence that active enforcement of age restriction laws on tobacco sales can lower the prevalence of smoking among teenagers. Unfortunately, active enforcement of tobacco age restrictions laws is the exception rather than the rule in most US communities.

Until recently, the federal government had taken no action to regulate the access of minors to tobacco. In July 1992, Congress passed an important amendment to the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) Reorganization Act designed to discourage tobacco use by young people. The Synar Amendment (named for Congressman Mike Synar, who offered this amendment to the ADAMHA bill) provides that, as a condition of receiving block grant funds for substance abuse prevention and treatment, states must enact and enforce a law prohibiting the sale or distribution of tobacco products to individuals under 18 years of age. Specifically, states are required to check retailer compliance with the tobacco age sale law by conducting random, unannounced inspections of locations at which tobacco products are sold and to submit a report to the secretary of health and human services describing their activities aimed at enforcing the law during the preceding year. If a state fails to demonstrate a reasonable effort to enforce the law preventing tobacco sales to minors, then it will lose between 10% and 40% (depending on the year) of its ADAMHA funds. ADAMHA block grant awards tentatively set for fiscal year 1993 range from $2.0 million for Wyoming to $201.2 million for California. Since no state wishes to risk losing substantial federal funding, the Synar Amendment provides a new impetus for state governments to enact meaningful legislation and enforce existing laws to curtail tobacco sales to minors.

Finally, policymakers should also consider increasing taxes on cigarettes as a strategy to reduce teenage smoking. In comparison with adults, teenagers have relatively little disposable income and are therefore more sensitive to increases in prices.[21] A recently completed Canadian study found that a 10% increase in the relative price of cigarettes (over and above inflation) resulted in a 14% decline in the prevalence of smoking by 15- through 19-year-old teenagers.[22] □

The *American Journal of Public Health* (*AJPH*), published monthly, is the official Journal of the American Public Health Association, Inc, 1015 15th St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005. *AJPH* allotted $40; *The Nation's Health* allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters. Printed in the United States.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on the first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, *AJPH* Reprints, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the Journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

The Effects of Specific Medical Conditions on the Functional Limitations of Elders in the Framingham Study

Andrew A. Guccione, PhD, PT, David T. Felson, MD, MPH, Jennifer J. Anderson, PhD, John M. Anthony, BS, BA, Yuqing Zhang, MB, MPH, Peter W. F. Wilson, MD, Margaret Kelly-Hayes, EdD, RN, Philip A. Wolf, MD, Bernard E. Kreger, MD, MPH, and William B. Kannel, MD

ABSTRACT

Objectives. The purpose of this study was to identify associations between specific medical conditions in the elderly and limitations in functional tasks; to compare risks of disability across medical conditions, controlling for age, sex, and comorbidity; and to determine the proportion of disability attributable to each condition.

Methods. The subjects were 709 noninstitutionalized men and 1060 women of the Framingham Study cohort (mean age 73.7 ± 6.3 years). Ten medical conditions were identified for study: knee osteoarthritis, hip fracture, diabetes, stroke, heart disease, intermittent claudication, congestive heart failure, chronic obstructive pulmonary disease, depressive symptomatology, and cognitive impairment. Adjusted odds ratios were calculated for dependence on human assistance in seven functional activities.

Results. Stroke was significantly associated with functional limitations in all seven tasks; depressive symptomatology and hip fracture were associated with limitations in five tasks; and knee osteoarthritis, heart disease, congestive heart failure, and chronic obstructive pulmonary disease, were associated with limitations in four tasks each.

Conclusions. In general, stroke, depressive symptomatology, hip fracture, knee osteoarthritis, and heart disease account for more physical disability in noninstitutionalized elderly men and women than other diseases. (*Am J Public Health.* 1994;84:351–358)

Introduction

Medical comorbidity in the elderly is well documented.[1] Furthermore, an increase in the number of coexistent conditions among elders is directly associated with an increase in limitations in activities of daily living.[1] Associations between disease and physical disability in the elderly have been found for arthritis,[2–8] hip fracture,[9] low back pain,[8,10] diabetes,[6,7,11,12] hypertension,[8,12] coronary heart disease,[13,14] cardiovascular disease,[15] mild heart trouble,[6] heart attack,[11] shortness of breath,[6] peak expiratory flow rate,[16] leg cramps,[6] depression,[17,18] stroke,[6,7,11,19,20] visual impairment,[7] breast cancer,[21] and cognitive deficits.[22] There is, however, no reason to assume that all conditions have similar impacts on function.

Previously, the relationship between arthritis and physical functional limitations in the elderly has been shown to be limited to those activities that require the individual to use the afflicted joint.[2] Other conditions may also have task-specific impacts on function. For example, an individual with heart or lung disease may be limited in activities requiring endurance but not in those that require only dexterity. Thus, in a disabled elder with multiple chronic conditions, the inability to perform certain tasks may be related either to the broad effects of a single condition on most or all activities of daily living or to the independent effects of several conditions, each of which affects only a few activities. Although it is common to adjust for age, sex, and other sociodemographic variables when investigating the association between a particular medical condition and physical disability in the elderly, few investigators have attempted to sort out the independent impacts of specific diseases on the physical function of elders when these conditions coexist.[23] If one goal of medical care for the elderly is to control or diminish the effects of disease on physical functional status, then we must understand which specific medical conditions are associated with which specific functional limitations.

Many investigations of the relationship between disease and disability have relied on self-reported disease, potentially hindering accurate assessment of the connection between specific medical conditions and physical function. Previous investigations have also been limited by statistical approaches that count the number of comorbid conditions or the

This paper was accepted June 23, 1993.

number of functional tasks affected, ignoring the potential task-specific nature of the relationship between disease and disability and the unequal effects of different conditions on function.

The overall aim of our investigation was to determine the independent effects of specific medical conditions on seven functional activities. Our study had three goals. The first was to identify the cross-sectional association in the Framingham cohort between specific medically validated diagnoses and functional limitations in two lower-extremity activities and five complex functional tasks. The second goal was to compare the risks of physical disability in elders for each medical condition, controlling for age, sex, and the presence of all other comorbid conditions. The final goal was to determine the proportion of disability in the cohort attributable to each medical condition, incorporating both the prevalence of the condition and the increased risk of functional limitation associated with it.

Method

Study Population

Our study population was the Framingham Study cohort. This cohort was enrolled between 1948 and 1951; the 5209 adults aged 28 through 62 constituted a one-third sample of Framingham residents in this age group. This group has been followed for more than 40 years; survivors are examined once every 2 years. With respect to mortality, fewer than 4% of the initial cohort of 5209 individuals have been lost to follow-up. At the time our data were collected, there were 2731 survivors. The data for this study are based on the 1826 elders who participated in the 18th biennial examination (1983 through 1985). The majority of nonparticipating survivors resided out of state and did not visit Framingham during the 2 years of the cohort examination.

Severe functional limitations in even the most basic activities of daily living have been documented for institutionalized elders.[24] We proposed to study higher levels of physical functional status, including instrumental activities of daily living such as grocery shopping and housekeeping, in noninstitutionalized elders. We limited our analyses to 1769 individuals who were not institutionalized at the time of their on-site participation in the 18th examination.

Definitions of Disease

All disease data were collected by trained study physicians and nurses and verified by a panel of physicians. We initially identified 20 medical conditions of potential interest in the data set available for study (Appendix A). We studied two musculoskeletal conditions: knee osteoarthritis and hip fracture. We allowed for two clinical presentations in our definition of knee osteoarthritis: (1) at least grade 2 radiographic changes according to the Kellgren and Lawrence criteria[25] with pain in or around the knee lasting at least a month in the year prior to examination; or (2) at least grade 3 radiographic changes (joint space narrowing plus osteophytes) with infrequent pain. In a previous study of knee osteoarthritis in the elders of the Framingham Study, it was found that those with infrequent symptoms and severe radiographic changes had increased odds of lower-extremity disability comparable to those of elders with symptoms but less severe radiographic changes.[2] Hip fracture was defined as fracture of the proximal femur prior to the 18th biennial examination.

There is evidence that obesity enhances the effects of arthritis on disability.[4] Therefore, we included obesity, defined as a body mass index (weight in kilograms divided by height in meters squared) of 30 or more, as the third medical condition in our preliminary analyses. Elders who used either insulin or oral hypoglycemics were counted as persons with diabetes.

Eight cardiovascular conditions were considered in the preliminary analysis of the relationship between a disease and disability. Hypertension was defined as a systolic blood pressure greater than or equal to 160 mm Hg and a diastolic blood pressure greater than or equal to 95 mm Hg at examination 18, without reference to treatment. Elders with cerebral vascular accidents, excluding transient ischemic attacks, prior to examination 18 were counted as persons with stroke. Specific criteria for angina pectoris, myocardial infarction on electrocardiogram, coronary insufficiency, and congestive heart failure have been developed for use at Framingham and are published elsewhere.[14] For the purposes of this study, we defined heart disease as any history of angina or myocardial infarction on electrocardiogram. We also included physician-diagnosed intermittent claudication as the final cardiovascular condition.

Three pulmonary disorders were defined for our preliminary analyses. First we examined dyspnea on exertion, although we recognized that it might be related to conditions other than lung diseases. Using spirometry performed at the previous biennial examination (1981 through 1983), we defined chronic obstructive pulmonary disease as ratio of forced expiratory volume in 1 second to forced vital capacity of less than 60%.[26] The third condition, symptomatic chronic obstructive pulmonary disease, was defined as chronic obstructive pulmonary disease on spirometry as defined above with dyspnea on exertion. Cancer was defined as any prevalent cancer except nonmelanoma skin cancer within the 5 years prior to an individual's visit at examination 18.

Mental status examinations are routinely conducted at Framingham.[27] As recommended by its developer, a score of less than 24 of a possible 30 on the Folstein Mini-Mental Status Examination was used to indicate cognitive impairment.[28] The 10-item Framingham screening measure of depressive symptoms is based on the CES-D (Center for Epidemiologic Studies–Depression Scale).[29] Each self-report item is scored dichotomously, indicating presence or absence of the symptom. We considered a score of 4 or higher at examination 18 as evidence of depressive symptomatology.

Data on cataracts and visual acuity were used to identify any association between visual impairment and functional limitations. We considered cataracts in either eye or both eyes. Although data on visual acuity at examination 18 were not available, we used data gathered at the 19th biennial exam on a subsample of elders and defined impairment as best-corrected vision worse than 20/40 in either eye.

Measures of Physical Disability

Data were collected on 16 measures of physical disability at examination 18. Six items measuring the most basic activities of daily living (e.g., bathing and toileting) were rejected for inclusion because we found little disability on these items, as might be anticipated in a sample of elders living independently in the community. Three items measuring

more complex activities (e.g., dialing a telephone) were rejected for the same reason. Of the seven remaining functional measures, two items covered activities explicitly involving the lower extremities: walking up and down stairs to the second floor and walking a mile. Each of these items was adapted from the Rosow-Breslau Functional Health Index[30] and had been used previously at Framingham. Five measures covered functional tasks requiring both upper and lower extremities: housekeeping; heavy home chores, including shoveling snow and washing windows; cooking; grocery shopping; and carrying bundles weighing 10 pounds. The item on heavy home chores came from the Rosow-Breslau Functional Health Index; the last item was taken from an instrument developed by Nagi.[31] The items on housekeeping, cooking, and grocery shopping had also been previously used at Framingham.[32]

For items from the Rosow-Breslau instrument, subjects were recorded as able or unable to do without help. The items on housekeeping, cooking, and grocery shopping asked whether the respondent could perform that activity entirely without help from another person. The item on carrying bundles was part of a physical performance battery administered by a study nurse.[33] For this item, subjects were scored as independent, dependent on an assistive device, dependent on human assistance, or unable to do. To make the definition of the dependent variable comparable across items, we chose the need for human assistance as the criterion of functional limitation for each of the seven dependent variables.

Data Analysis

To pare our list of diagnoses using both clinical and statistical criteria, we evaluated the strength of the association of each of the initial 20 conditions with disability in each of the seven functional tasks. We considered whether the condition had clinical relevance to any one of the functional activities (e.g., intermittent claudication and walking) and whether the age- and sex-adjusted relative risk was at least 1.5. On the basis of these criteria, we identified 10 prevalent medical conditions associated with physical disability in the Framingham cohort: knee osteoarthritis, hip fracture, diabetes, stroke, heart disease, congestive heart failure, intermittent claudication, chronic obstructive pulmonary disease, depressive symptomatology, and cognitive impairment. The specific criteria for these diagnoses are found in Appendix B.

We used logistic regression analyses to calculate prevalence odds ratios for dependence in performing each of the seven functional tasks. All elders were used as the referent group in these calculations so that these odds ratios are estimates of relative risk. An odds ratio was defined as the odds of functional dependence in performing a functional task among subjects with a specific medical condition divided by the odds of dependence in that task among all subjects. Because we had noted a high degree of association between heart disease and congestive heart failure, we did not adjust for the presence of heart disease in the sample when calculating the odds of disability for elders with congestive heart failure. We did, however, include both conditions when adjusting for all noncardiac conditions.

In each of the seven logistic regression equations for a particular condition, we controlled for sex, for age as a continuous variable, and for the presence of each of the 10 medical conditions to calculate an adjusted odds ratio (aOR). The adjusted odds ratio was computed with 95% confidence intervals based on maximum likelihood–derived standard errors.

To understand the impact of each condition in terms of its prevalence as well as its odds of disability, we also computed the proportion of dependence in a particular task attributable to each condition as an adjusted attributable fraction (AF).[34] We calculated the adjusted attributable fraction in this study using the formula

$$AF = [(p)(aOR - 1) \div aOR],$$

where p is the proportion of functionally limited elders with a specific disease.

We had obtained knee radiographs on 1416 subjects in our sample. To maintain the size of our sample for this study, we used age, sex, and knee symptoms to impute knee osteoarthritis to elders who had participated in examination 18 but did not have radiographs. Our data on osteoarthritis includes the imputation of knee osteoarthritis to 61 elders. We compared analyses with and without these imputed cases and found no differences; therefore, imputed cases of knee osteoarthritis are included in the results below.

TABLE 1—Age Breakdown of Study Sample (n = 1769)

	Men (n = 709)		Women (n = 1060)	
	No.	%	No.	%
≤69 y	260	36.7	353	33.4
70–79 y	328	46.3	518	48.9
≥80 y	121	17.1	188	17.7
Mean ± SD	73.4 ± 6.3		73.9 ± 6.4	
Range	64.1–92.1		63.8–94.6	

Results

The age breakdown of the sample is shown in Table 1. There were 1060 women and 709 men; the mean age was 73.7 years. The prevalence of the 10 medical conditions included in our analyses and the proportion of elders with at least one comorbidity for each disease are found in Table 2. We found heart disease and knee osteoarthritis the most prevalent and hip fracture and congestive heart failure the least prevalent of these diseases.

The prevalence of dependence in each of the seven functional activities is found in Table 3. Dependence was substantially more frequent for heavy home chores, which require upper and lower extremity use, and walking a mile, one of the two lower-extremity items; dependence in cooking was found least often.

The age-, sex-, and comorbidity-adjusted odds ratios for dependence in each activity are found in Table 4. Only stroke was significantly associated with dependence on human assistance for all seven tasks. Depressive symptomatology and hip fracture were each significantly associated with functional limitations in five tasks. Four conditions were associated with dependence in four tasks each and posed risks of similar magnitude: knee osteoarthritis, heart disease, congestive heart failure, and chronic obstructive pulmonary disease.

The largest proportions of subjects dependent on others in stair climbing were among elders with hip fracture or congestive heart failure. Increased odds of dependence in stair climbing were also seen for elders with knee osteoarthritis, diabetes, stroke, chronic obstructive pulmonary disease, and depressive symptomatology. The proportion of elders

TABLE 2—Prevalence of Conditions

Condition	No. Affected/ Total n	%	% with at Least One Other Condition
Knee osteoarthritis	318/1726	18.4	50.0
Hip fracture	62/1769	3.5	69.4
Diabetes	110/1758	6.3	69.1
Stroke	122/1769	6.9	71.3
Heart disease	324/1769	18.3	66.4
Congestive heart failure	56/1769	3.2	92.9
Claudication	124/1769	7.0	77.4
Chronic obstructive pulmonary disease	113/1724	6.6	58.4
Depressive symptomatology	152/1668	9.1	57.2
Cognitive impairment	139/1704	8.2	67.6

Note. "Total n's" may not equal 1769 because of missing data.

Grocery shopping	113/1558	7.3
Carrying bundles	89/1643	5.4

Note. "Total n's" may not equal 1769 because of missing data.

dependent in walking a mile was substantial for every condition. Elders with hip fracture and stroke had the greatest odds of limitation in this activity.

For each of the 10 conditions, more elders were limited in performing heavy home chores than in any other activity. The odds of dependence in performing heavy home chores were particularly striking for elders with stroke, heart disease, and congestive heart failure. Dependence in light housekeeping was not common. The strongest associations were found for elders with hip fracture, stroke, and congestive heart failure. Elders with knee osteoarthritis, heart disease, chronic obstructive pulmonary disease, and depressive symptomatology also had substantial odds of dependence in this activity.

Few elders with any medical condition were functionally limited in cooking. The strongest associations between a medical condition and a functional limitation in cooking were found for elders with stroke or diabetes. The largest proportion of elders who were dependent in grocery shopping were subjects who had sustained a hip fracture at some time prior to examination 18. Dependence in grocery shopping was most strongly associated with stroke. Elders with hip fracture, heart disease, and depressive symptomatology also had increased odds of dependence in grocery shopping. The risk of dependence in carrying bundles was greatest for elders with congestive heart failure, who also constituted the largest proportion of elders limited in this activity. Knee osteoarthritis, stroke, and depressive symptomatology were also strongly associated with dependence in carrying bundles.

The percentage of functional limitation in each task attributable to each medical condition after adjustments were made for age, sex, and comorbidity is found in Table 5. Most conditions account for at least 7% of the disability in at least one activity. Comparisons of the magnitude of these fractions across all activities, however, draw attention to one diagnosis in particular: stroke. Although attributable fractions of similar magnitude in every functional task were found for some other conditions, depressive symptomatology accounts for a substantial proportion of the limitations in each of the five functional tasks. Knee osteoarthritis and heart disease each contribute to limitations in at least four tasks, only two of which (walking a mile and light housekeeping) are the same for both conditions. The proportion of limitations in either of these activities that is associated with knee osteoarthritis is substantially greater than the proportion attributable to heart disease.

Discussion

We identified 10 prevalent medical conditions associated with disability in elders: knee osteoarthritis, hip fracture, diabetes, stroke, heart disease, congestive heart failure, intermittent claudication, chronic obstructive pulmonary disease, depressive symptomatology, and cognitive impairment. Our findings indicate that these 10 medical conditions impose functional limitations on the elderly that are specific to each disease and to each activity. After adjustment for coexisting medical conditions, stroke, depressive symptomatology, hip fracture, knee osteoarthritis, heart disease, congestive heart failure, and chronic obstructive pulmonary disease demonstrated significant and substantial associations with limitations in at least four of the seven functional activities studied. The largest proportions of disability were attributable to knee osteoarthritis, heart disease, depressive symptomatology, and stroke.

The results of this study corroborate the findings of other studies. Despite its low prevalence, stroke, which limits a broad array of functional activities, is one of the main disabling conditions of the elderly. Our sample included only noninstitutionalized survivors of stroke and excluded those who may have been functionally incapacitated by stroke to the point of needing nursing home placement. Thus, with respect to all elders, the disabling effects of stroke may be even greater than our results indicate. Previous studies, including those done at Framingham,[19,20] have indicated a relationship between stroke and disability in the total number of activities that were limited. The data presented above clarify the magnitude of this relationship. Our study also demonstrates the global effect of stroke on function, which follows from the pattern of upper- and lower-extremity neuromuscular impairments typically seen in the patient with stroke. Similarly, our findings support the observations of Harris et al.[15] and Guralnik and Kaplan[8] regarding arthritis and cardiovascular disease and their relationship to disability in the elderly.

The conclusions on the relationship of cardiovascular diseases to physical disability in the elderly that are supported by our data are somewhat differ-

TABLE 4—Odds of Disability, Adjusted for Age, Sex, and Comorbidity, by Condition and by Activity

[a]Adjusted odds ratio < 1.

ent from those reached by other investigators at Framingham.[14] We found substantial effects for cardiovascular disease including congestive heart failure. Previous analyses of physical disability in the Framingham cohort may have been unable to detect relationships when the cohort was younger and therefore less disabled. Furthermore, our analyses indicate that there is some task-specificity in the disability associated with cardiovascular disease. Summating the number of functionally limited activities may obscure the relationship between some cardiovascular diseases and limitations in particular activities.

The diminution of the effects of cognitive impairment after adjustment for comorbidity is striking. Although the relationship between cognitive and functional decline has been well accepted, it is clear that much of the disability associated with cognitive impairment among noninstitutionalized individuals may be due to other causes. It is also possible that the functional measures we chose do not capture the specific tasks that are most affected by cognitive impairment in a community-dwelling population. In contrast, however, the effects of depressive symptomatology on function remain even after adjustment for the comorbidities included in our study. Previously, Wells and colleagues found that adults with a current depressive disorder or depressive symptoms had worse physical, social, and role functioning than their peers without such conditions.[35] Our finding highlights the contributions of psychological factors to physical functional limitations in the elderly. Physical disability is not merely the end result of physical conditions. Successful performance of many functional activities, such as housekeeping, requires motivation and cognitive abilities as well as physical ones.

It is also important to comment on two of the conditions for which we were unable to find a relationship between disease and disability, namely cancer and visual impairment. It was surprising to us that prevalent cancers were not related to functional limitations in the elderly. Satariano et al., for example, have found difficulty in activities requiring primarily upper-extremity strength among women with breast cancer aged 55 through 74, but not among those aged 75 through 84.[21] Although our five complex activities of daily living required the use of both upper and lower extremities, we could not find any consistent relationship between cancer and disability in our preliminary analyses. The mean age of our sample approximates the age of the group in Satariano's sample who were no more disabled than the control subjects. It is quite possible that those elders in Framingham with the most disabling forms of cancer had died of it or did not participate in the study; therefore an older cohort such as ours may include only elders with less disabling cancer. Although visual impairment may increase the risk of falls and other accidents among the elderly, it does not appear to be related to functional limitations in the tasks we evaluated. It is also possible that the criterion of visual impairment we used (best-corrected vision of 20/40) may not be severe enough to identify those elders whose functional limitations may be associated with impaired ability to see.

Verbrugge and her colleagues reported on the relative impact of comorbid conditions on functional limitations in all adults aged 55 years or older included in the Supplement on Aging to the 1984 National Health Interview Survey.[36] Considering each disease separately and adjusting for age, sex, and race, Verbrugge et al. found that highly prevalent conditions generally had little impact on an elder's difficulty in performing functional activities. Conversely, several low-prevalence conditions were strongly associated with increases in the total number of gross mobility tasks and basic and instrumental activities of daily living that elders performed with difficulty or were unable to do. Arthritis was shown to be the sole exception to this general conclusion, as it was a highly prevalent disease with a moderate correlation with difficulty in performing an overall number of physical functional tasks. Our analyses corroborate and extend the conclusions of Verbrugge et al. However, it should be noted that our definition of medically verified arthritis was limited to the knee. If we had included hand, wrist, and hip arthritis, the functional impact of "all arthritis," the definition used by Verbrugge et al. for self-reported arthritis and in calculating the proportion of disability attributable to arthritis, would have been even greater.

The conclusions of our study are limited in several ways. Our data were collected at the Framingham study site. Therefore, some individuals may have been excluded because they were functionally limited by their medical conditions to the point of being unable to come to the site. The nonparticipation of these individuals would weaken the association of disease and disability in our results.

Another limitation of this study may be the definitions we chose to use for each of the medical conditions, despite the accuracy of data verified medically. As we have shown for knee osteoarthritis, the risks of disability change with the stringency of the definition of the disease.[2] We can assume that the risks of disability for any other condition we studied would change if the criteria for the condition were modified. When confronted with the possibility of defining a condition in several ways, we chose conservative criteria that we believed would also be clinically meaningful. Furthermore, our study was concerned only with the association between a single condition and physical disability after all other medical conditions were controlled. We did not examine how various combinations of medical conditions might be associated with increased risk for disability in the elderly. Our understanding of disability in the elderly should not, however, be confined merely to the study of disease and disability. Future research must also account for the contributions of psychological and social factors—for example, personal motivation and social support—to specific physical functional limitations.

Our study is also limited by the functional tasks that were available for study. Although these items are traditionally used in broad epidemiological studies of disability in the elderly, they are only a very small sample of functional activities. Other data, not available at Framingham, might be able to demonstrate similarly strong associations between our 10 target conditions and other functional tasks. A change in dependent variables might also yield substantial odds of disability for some of the conditions that did not appear strongly associated with functional limitations in our study. For example, it is very likely that the odds of functional limitation in elders with cognitive impairment would have been greater if we had chosen basic hygiene and self-care activities of daily living as measures of disability.

The results of this study have public policy implications. The emphasis in geriatric health care and prevention has only recently been on functional morbidity. The relationship between stroke and functional limitations in the elderly is broad, involving a host of activities. Reductions in stroke and its aftereffects should yield improvements in the functional abilities of elders in a variety of tasks. Similar gains in physical function might be realized through prevention of depressive symptomatology and hip fracture. In contrast, the relationships of knee osteoarthritis and heart disease to function are more closely tied to specific activities. Thus, practitioners must carefully link a functional deficit to its most likely medical cause to diminish the effects of these diseases on function. Clinically, as demonstrated by the high degree of medical comorbidity in our subjects, these medical conditions are likely to be coexistent. Successful evaluation and treatment of an elderly patient will require a careful examination of the independent contributions of each of the patient's medical diagnoses to his or her physical functional status.

In summary, we investigated the effects of 10 medical conditions on seven functional limitations in the elderly. Only one condition, stroke, contributed to limitations in all seven activities. The proportions of disability in the elderly attributable to knee osteoarthritis, stroke, heart disease, and depressive symptomatology were greater than the proportions of disability attributable to other conditions. Efforts to reduce the effects of certain medical conditions on the functional status of the elderly will be enhanced by our understanding of the disease- and task-specificity of these relationships. □

APPENDIX A—Medical Conditions Included in Preliminary Analyses

- Musculoskeletal
  - Knee osteoarthritis
  - Hip fracture
- Endocrine
  - Obesity
  - Diabetes
- Cardiovascular
  - Hypertension
  - Stroke excluding transient ischemic attack
  - Angina pectoris
  - Myocardial infarction
  - Coronary insufficiency
  - Heart disease
  - Congestive heart failure
  - Intermittent claudication
- Pulmonary
  - Dyspnea on exertion
  - Chronic obstructive pulmonary disease
  - Chronic obstructive pulmonary disease with dyspnea on exertion
- Oncologic
  - Cancers except nonmelanoma skin cancers
- Psychological
  - Depressive symptomatology
  - Cognitive impairment
- Visual impairment
  - Cataract
  - Visual acuity

APPENDIX B—Definitions of Medical Conditions

Knee osteoarthritis: Symptomatic osteoarthritis defined as pain in or around the knee lasting at least a month and at least grade 2 x-ray changes or asymptomatic osteoarthritis at least grade 3 on x-ray.

Hip fracture: Any hip fracture sustained prior to exam 18 visit.

Diabetes: Currently treated diabetes based on use of oral hypoglycemics or insulin.

Stroke: Sudden onset of a focal neurological deficit lasting more than 24 hours prior to exam 18 visit, excluding transient ischemic attacks.

Heart disease: Either angina pectoris or definite myocardial infarction on electrocardiogram any time prior to exam 18 visit.

Congestive heart failure: Condition meeting a minimum of two major criteria (e.g., paroxysmal nocturnal dyspnea or orthopnea, neck vein distension, cardiomegaly, acute pulmonary edema, rales, or S_3 gallop) or one major criterion and two minor criteria (e.g., bilateral ankle edema, dyspnea on exertion, tachycardia, or night cough).

Claudication: Intermittent claudication diagnosed by Framingham physicians.

Chronic obstructive pulmonary disease: $FEV_1 \div FVC < 60\%$ by spirometry at exam 16 or 17.[a]

Depressive symptomatology: A score of more than 4 of 10 on a modified CES-D scale with 10 questions.

Cognitive impairment: A score of less than 24 on the Folstein Mini-Mental Status Examination.

[a] FEV_1 = forced expiratory volume in 1 second; FVC = forced vital capacity.

US Dietary Patterns Associated with Fat Intake: The 1987 National Health Interview Survey

ABSTRACT

Objectives. This research used food frequency data to investigate dietary patterns associated with fat intake.

Methods. Data from the 1987 National Health Interview Survey of 20 143 adults were used to determine correlations between fat (adjusted for kilocalories) and both nutrient and food group intakes. Median food and nutrient intakes were determined within quartiles of percentage of kilocalories from fat.

Results. Intakes of vegetables, fruits, cereals, fish/chicken, low-fat milk, alcoholic beverages, vitamin C, percentage of kilocalories from carbohydrates, carotenoids, folate, dietary fiber, carbohydrates, and vitamin A decreased as percentage of kilocalories from fat increased. Intakes of salty snacks, peanuts, processed and red meats, whole milk and cheese, desserts, eggs, fried potatoes, table fats, cholesterol, vitamin E, sodium, protein, and energy increased with percentage of kilocalories from fat. Results by demographic subgroups showed few differences from those found in the total population.

Conclusions. Fat intake is consistently associated with specific dietary patterns. Such patterns need to be evaluated concurrently in studies of diet and chronic disease. (*Am J Public Health.* 1994;84:359–366)

Introduction

In the last 2 decades, there has been increasing interest in the role of dietary fat in chronic disease. The consensus among major scientific organizations is that fat intake should be reduced below current levels in the United States to reduce the risk of heart disease, cancer, and obesity[1–6]; the most common recommendation is that individuals reduce their fat intake to 30% of calories (kilocalories) or less.[3,4,6] Many of these organizations recommend concurrent dietary guidelines that include increased fruit and vegetable intake to five daily servings,[2,3,6] increased intake of whole grains and dietary fiber,[1,3–6] and reduced sodium intake.[1–6] When individuals change their fat intake, however, a variety of other dietary changes may occur to balance caloric intake. Food selections are based on food preference and availability, budget, social environment, and other factors. A low-fat diet can be implemented in a variety of ways: increasing intake of fruits, vegetables, complex carbohydrates, and/or low-fat dairy products and decreasing intake of meats, table fats, whole milk and cheese, and/or baked goods. These choices may produce quite different dietary patterns, many of which could constitute a diet low in fat. Two recent studies[7,8] examined dietary patterns and fat intake in small numbers of women (172 and 17, respectively) volunteering for clinical trials designed to reduce fat intake. The purpose of the present study is to quantify the relationships between dietary patterns and diets either low or high in fat among 20 143 adults interviewed in the nationally representative 1987 National Health Interview Survey (NHIS).

Methods

The 1987 NHIS, conducted by the National Center for Health Statistics, was administered throughout calendar year 1987 to 44 123 individuals and had a response rate of 82%. The survey was designed to represent US households in the 48 contiguous states.[9] One adult per household was randomly selected to be administered the Cancer Risk Factor Supplement, developed and funded by the National Cancer Institute. Details regarding the methodology of the Cancer Risk Factor Supplement and the collection of dietary data can be found elsewhere.[10] Briefly, in a split-sample design, either the cancer control or the epidemiology questionnaire was administered. Door-to-door, in-home interviews of non-institutionalized individuals were conducted by experienced Bureau of the Census interviewers. For respondents not found at home after repeated visits, interviews were obtained by telephone whenever possible (approximately 16%). Hispanics were oversampled, and a Spanish translation of the interview was used when necessary.

[a]Quartile cutpoints for percentage of kilocalories from fat were 33.9%, 38.8%, and 43.3%.

The dietary interview, consisting of a 59-item food frequency questionnaire developed by Block et al.,[11] was administered to 22 080 adults and lasted an average of 17 minutes. Individuals were asked to report the number of times per day, week, month, or year they consumed each food item. Portion size was asked for each food item (small, medium, or large), and age- and sex-specific portion sizes were used to estimate nutrient intake.[12] The 59 food items included on the questionnaire were selected to represent the foods that were the major contributors of nutrients in adult diets based on analyses of nutrient sources[13,14] from 24-hour dietary recall data collected in the second National Health and Nutrition Examination Survey (NHANES II) during 1976 through 1980. The longer 98-item questionnaire on which this instrument was based was validated in several studies[15–18] and has shown good ranking of individuals and reasonable estimates of mean nutrient intake. Correlations between nutrients estimated by multiple days of diet records or the 59-item questionnaire were comparable to those found with the longer version.[11] Of the 22 080 adults who were administered the questionnaire, approximately 6% were excluded from analysis because of coding, interviewer, or respondent error, as were individuals reporting a racial or ethnic identification other than White, Black, or Hispanic. Data on 20 143 individuals were analyzed.

Nutrient estimates were calculated with the database and software developed by Block et al. based on the NHANES II food database.[12] In comparison with the 98-item questionnaire, the 59-item instrument tends to underestimate absolute intake of macronutrients and some micronutrients but may overestimate vitamins A and C. However, percentage of kilocalories from macronutrients is considered accurate.[19] Because of this concern about estimates of absolute intake, relative intake and dietary patterns are emphasized. Adjustment coefficients[19] were not used. The 59 food items were categorized into groups (not always mutually exclusive) based on nutritional, functional, and botanical similarities, and total servings per week were calculated (a description of the food groups is available on request).

Individuals were categorized by their percentage of kilocalories from fat, a measure widely recognized as of interest to public health. First, distributions were examined separately by sex, by race/ethnicity, by age (19 through 34, 35 through 49, 50 through 64, 65+ years), and by eight sex-age groups. Distributions for all subgroups were nearly identical, except for Hispanics, who had somewhat lower percentages of intake of kilocalories from fat. Thus, subjects were assigned to quartiles of percentage of kilocalories from fat based on the total population. Medians for nutrient and food group intake were examined by quartile for all age–sex groups and by race/ethnicity, education (<12, 12, >12 years), and household income (<$14 000, $14 000 through $29 999, $30 000 through $49 999, ≥$50 000). Three methods were used in examining correlations between fat intake and nutrient/food group intake controlling for total caloric intake. The first method involves Pearson product moment correlations between absolute nutrient intake and percentage of kilocalories from fat, a commonly used procedure yielding results that can be compared with those of other studies. The second method computes Pearson correlations between age- and sex-specific percentiles of nutrient intake and percentage of kilocalories from fat. The use of percentiles adjusts nutrient intake for age and sex differences. In addition, this procedure has the advantage of not being unduly influenced by extreme values of nutrient intake. The third method uses partial correlations between the nutrient/food group and total fat intake adjusting for kilocalories, age, and sex. All correlations and median intake values were calculated by using sample weights in SAS[20] and SUDAAN.[21]

Results

The mean percentage intake of kilocalories from fat for the entire NHIS population was 38.4% (range = 6.0% to 71.6%). Weighted quartile cutpoints for percentage of kilocalories from fat were 33.9%, 38.8%, and 43.3%. Table 1 shows the number and percentage of individuals in each quartile by demographic subgroup. Hispanics were more likely to be in the lowest quartile than were Whites or Blacks. The percentage of individuals in the lowest quartile increased consistently with age, while the percentage in the third quartile de-

creased from the youngest age groups to those 50 or older. Analyses by education and income showed that both the wealthiest and the most educated were more likely to consume a low percentage of kilocalories from fat.

Table 2 shows that the correlation coefficients between nutrient intake and fat adjusted for kilocalories obtained with the three methods described above were quite similar. Exceptions were oleic acid, saturated fat, and carbohydrate, for which the partial correlations with fat adjusted for calories were noticeably larger than either correlation with percentage of kilocalories from fat. On the basis of the overall similarity of the three approaches, additional analyses used simple correlations.

The correlations for macronutrients (Table 2) show that total fat and fat constituents (oleic acid, saturated fat, linoleic acid, and cholesterol) were most highly positively correlated with percentage of kilocalories from fat (r's ranging from −.29 to .42). Protein (r = .13) and carbohydrate (r = −.19) had low correlations, with protein increasing and carbohydrate decreasing with increased percentage of kilocalories from fat. The percentages of kilocalories from fat and from carbohydrate were strongly negatively correlated (r = −.73), compared with only a slight positive correlation for percentage of kilocalories from protein (r = .08). Energy intake had a low positive correlation (r = .07) with percentage of kilocalories from fat.

Of the micronutrients, vitamin C had the largest negative correlation with percentage of kilocalories from fat (r = −.32). Folate, dietary fiber, and carotene also had negative correlations (r's of approximately −0.2), and vitamin E and sodium had positive correlations of similar magnitude. Correlations were less than ±.10 for all other nutrients. Simple correlations with percentage of kilocalories from fat for all nutrients in Table 2 were also determined by sex, four age groups, three race groups, three education groups, and four income groups to investigate differences from the total population correlations. Of the 400 possible correlations, only 7 (2%) varied by ±.10 from the population correlation, and no consistent patterns emerged.

Table 3 shows the absolute median intake of nutrients by percentage of kilocalories from fat quartile and the ratio of medians in quartile 4 to medians in quartile 1. Nutrients are listed in descending order by ratio. The similar order of the nutrients in Table 2 (by correlation coefficient) and Table 3 (by ratio) suggests relative consistency in their associations with percentage of kilocalories from fat. Energy intake was 14% greater for individuals in the highest compared with the lowest quartile. For fat and its constituents, the differences were more dramatic, with intakes of oleic acid, saturated fat, linoleic acid, and total fat almost twice as great, and cholesterol two thirds as great in the fourth as in the first quartile. Similar to energy, intake of protein was 17% greater in the fourth than the first quartile. Intake of total carbohydrate in the fourth quartile was about one quarter of that in the first, while percentage intake of kilocalories from carbohydrate was three quarters of that in the first.

Results for micronutrients and fiber showed a trend for intakes of vitamin C, dietary fiber, folate, and carotene, all of which are found primarily in fruits and vegetables, to be lowest in the highest quartile. The gradient was most striking for vitamin C, with intake in the fourth quartile about 60% of that in the first. Intakes of dietary fiber, folate, and carotene among those in the highest quartile were all about three fourths of those in the lowest. In contrast, intakes of sodium and vitamin E were higher in the fourth quartile than in the first (1.24 and 1.33 times as great, respectively). Other nutrients varied little by quartile. While absolute intake of nutrients varied by age and sex (data not shown), the overall pattern of nutrient intake by percentage of kilocalories from fat differed little when ratios were compared (the largest ratio range [1.17 to 2.03] involved saturated fat). Examination of comparable ratios by education, income, and race showed that of the 250 ratios calculated, 2 differed by more than ±.20 from the population ratio.

Table 4 provides correlations between intake of food groups (number of servings per week) and percentage of kilocalories from fat. Results for all three methods were essentially the same, with the exception of alcoholic bever-

[a]Quartile cutpoints were 33.9%, 38.8%, and 43.3%.
[b]Ratio of quartile 4 to quartile 1.

ages, and simple correlations were used in further analyses. Servings of table fats and "all meats" represented the food group most highly positively correlated with percentage of kilocalories from fat (approximately .35). The "all meat" subgroups (processed meats and red meat) had positive correlations, while fish and chicken were essentially uncorrelated. Eggs, cheese, and whole milk were also positively correlated ($r = .21$) with percentage of kilocalories from fat, while low-fat milk was negatively correlated ($r = -.19$). The "all breads" food group and starches, representing good sources of complex carbohydrates, showed essentially no correlation to percentage of kilocalories from fat. Fried potatoes alone did, however, show a low positive correlation ($r = .14$). High-fiber bread/cereal and ready-to-eat cereals showed low negative correlations ($r < .20$). Without exception, fruits and vegetables (not including potatoes), as a single food group ($r = -.27$) and when divided into subgroups, were negatively correlated with percentage of kilocalories from fat; the fruit and juice group and the citrus fruit group showed the strongest negative correlations. Alcoholic beverages were inversely correlated with percentage of kilocalories from fat ($r = -.29$). However, the partial correlation between alcoholic beverages and grams of fat (controlling for age, sex, and kilocalories) was $-.50$. As in the case of nutrients, simple correlations were computed for percentage of kilocalories from fat with all food groups by age, sex, race, education, and income subgroups. Of the 432 possible correlations for all food groups by each demographic factor, only 3 were more than $\pm.10$ from the total population simple correlation.

Table 5 shows the median number of servings per week of food groups within each quartile, as well as the ratio of servings per week in the fourth to first quartile in descending order. In comparison with nutrients, the ratios for foods were generally greater. Food groups with the strongest correlation coefficients in Table 4 also tended to show the greatest differences in absolute intake across quartiles. Salty snacks and peanuts had the highest ratios. Absolute servings of table fats were almost twice as great among individuals in the highest than in the lowest quartile. Those in the highest quartile reported eating meat ("all meat" group) more than 10 times per week, as compared with about 6 times per week for those in the first quartile. Results for red and processed meat were consistent with this finding, showing intakes 1.7 and 3.2 times as great in the fourth than in the first quartile, respectively. Servings of fish and chicken in the fourth quartile, however, were 80% of those in the first. Intake of whole milk and cheese was 2.5 times higher in the upper quartile, while low-fat milk intake declined to a median of zero from the first to the fourth quartile. Intake of starches, nonfried potatoes, and all breads showed no major differences across quartiles, but intake of fried potatoes was two times as great in the fourth than in the first quartile. Intake of both ready-to-eat cereal and high-fiber bread/cereal was about half as great in the fourth as in the first quartile. Intakes of fruits and vegetables combined, vegetables excluding potatoes, and fruits alone were all lower among those in the highest quartile. For citrus fruits (primarily oranges) and for fruits and juice, the differences in intake between those in the lowest and highest quartiles were twofold to threefold. Alcoholic beverage intake in the highest quartile was one eighth that in the lowest quartile.

Median intake of food groups and the ratio of quartile 4 to quartile 1 were also determined by race, education, and income categories (results available on request). For salty snacks, peanuts, and low-fat milk, meaningful ratios could not be calculated as a result of zero median intake in quartile 1 or quartile 4. For all meat, all bread, all vegetables, garden vegetables, fruits and vegetables, and citrus fruits, there were no ratio differences greater than $\pm.20$ from the total population ratio presented in Table 5. For the other 18 food groups, 42 of a possible 180 ratios varied from the total population ratio by greater than $\pm.20$, and 22 were greater than $\pm.50$. However, no particular demographic subgroup emerged that had a clear pattern of difference from the total population.

Heavy alcohol consumers tended to be categorized as having a low percentage of kilocalories from fat in their diets. The heaviest drinkers (primarily 18- to 34-year-old men) were easily categorized into what appeared to be the healthiest diet. However, when we either eliminated those consuming more than 20 alcoholic drinks per week from the analyses or removed all kilocalories from alcoholic beverages, establishing new quartile cutpoints for percentage of kilocalories from fat, our overall results regarding either correlations or absolute intake of nutrients or food groups did not change. Therefore, no exclusions were made on the basis of alcohol consumption, allowing for the reality of alcohol intake in the US diet.

Discussion

We have shown, in nationally representative data, that the percentage of kilocalories from fat in the diet is consistently correlated with specific nutrients and food groups across demographic variables of age, sex, race, education, and income, and we found a consistent pattern in the relative change in nutrient and food group intake across quartiles by demographic subgroups. Some of our findings are surprising, while others are not. Given that percentage of kilocalories from fat is different from absolute fat intake, it does not necessarily follow that all foods with substantial fat content will necessarily highly correlate with percentage of kilocalories from fat. The strength of the correlation depends on amount consumed and on fat and caloric content. As expected, high positive correlations were found between percentage of kilocalories from fat and both fat constituents and high-fat food groups. The negative correlations with vitamin C, folate, fiber, carbohydrate, and carotene and associated food groups, however, were less expected. Fruits, vegetables, low-fat milk, and ready-to-eat cereal appear to contribute to a diet low in percentage of kilocalories from fat because they are rich in carbohydrates and substitute carbohydrate kilocalories for fat kilocalories and also because they may be part of a dietary pattern that includes fish and chicken and limits red meats, processed meats, table fats, and eggs. It appears that as individuals decrease their percentage of kilocalories from fat, they substitute primarily carbohydrate- rather than protein-rich foods for energy replacement, partly because protein and fat occur together in many foods.

TABLE 4—Correlations Between Fat and Food Group Intake (Servings per Week): National Health Interview Survey, 1987

Food Group	Simple Correlation[a]	Percentile Correlation[b]	Partial Correlation[c]
Table fats	.37	.38	.37

[a]Pearson correlation of percentage of kilocalories from fat with absolute intake.
[b]Pearson correlation of percentage of kilocalories from fat with age- and sex-specific percentile of intake.
[c]Correlation of grams of fat with absolute intake (controlling for age, sex, and kilocalories).

It is surprising that intakes of nonfried potatoes, starches, and breads changed little with quartiles of percentage of kilocalories from fat since these are foods that Americans are encouraged to consume for purposes of achieving a low-fat diet. In part, this is because of the fats frequently added to these foods (reflected in the NHANES II database used here) that increase their percentage of kilocalories from fat. Furthermore, the stability of these starchy food groups across quartiles suggests that they are staples at all levels of fat intake. Total dairy product intake varied little by fat quartile. However, when the dairy product category is divided into low-fat milk and whole milk and cheese, there is an obvious split in the data indicating that individuals generally consume foods in one group or the other. It is clear that low-fat dairy products can fit easily into a diet low in percentage of kilocalories from fat. Eggs and fish/chicken are both considered medium- to low-fat sources of animal protein, depending on cut and preparation factors. However, in our data, eggs were positively correlated with high-fat diets, while fish/chicken (fried varieties included) were not. These data suggest that eggs are associated with other high-fat eating practices, while fish/chicken consumption characterizes individuals who are not consuming a high-fat diet.

Our analysis focused on the relationship of dietary patterns with fat adjusted for calories, not with absolute fat intake. Because several different techniques are now in use to adjust fat for calories,[22] we used three methods to estimate correlation coefficients with nutrients and food groups. All three methods provided similar results.

Few studies have evaluated data regarding nutrient and food group intake on large representative samples as it relates to percentage of kilocalories from fat. Two small studies, however,

TABLE 5—Median Number of Servings per Week of Foods, by Percentage of Kilocalories from Fat Quartiles: National Health Interview Survey, 1987

Food	Quartile %[a]				Ratio[b]

have investigated changes in total diet as a result of dietary interventions designed to reduce fat intake.[7,8] These intervention studies measured somewhat different effects, since the participants were volunteers motivated by being at high risk for breast cancer and were given detailed instruction in decreasing fat to 15% to 20% of kilocalories while maintaining an adequate overall diet. Furthermore, individuals in our lowest quartile had a median intake of 30% of kilocalories from fat, a value much higher than the mean of approximately 22% achieved in the studies just mentioned.[7,8] Although 4-day food records were used to measure dietary intake in these studies, rather than the food frequency questionnaire approach used here, we nevertheless found similar dietary patterns associated with a low percentage of kilocalories from fat. Absolute mean intake of carbohydrate and protein in the low-fat diets declined very little (10% or less) in both of these studies, while total kilocalorie intake declined by about 25%. Our results show, on the basis of median intake, that individuals with low-fat (30% kilocalories from fat) compared with high-fat diets (46% kilocalories from fat) consume moderately less protein (17%) and energy (14%) but more carbohydrate (22%). In these studies, as in ours, absolute intakes of vitamins A and C[7,8] and folate[8] were higher in the low-fat diets, while calcium, thiamin, riboflavin, and niacin were not greatly affected. With respect to food groups, our data show dietary patterns similar to these studies; subjects with lower relative to higher fat diets reported consistently higher intakes of fruits[7,8] and vegetables,[8] and lower intakes of red and/or processed meat,[7,8] table fats,[7,8] desserts,[7,8] and salty snacks.[8]

Ursin et al.[23] conducted similar analyses of 10 306 adults using a more extensive 93-item food frequency questionnaire administered at the 1982 through 1984 follow-up of the NHANES I cohort. Although this questionnaire and the one used in the present study are different in length, the results for simple correlations between percentage of kilocalories from fat and either nutrient or food group intake are striking in their similarity. Results between the two studies regarding median intake of nutrients and food groups by percentage of kilocalories from fat quartile show that, in general, more marked differences appear in our data moving across quartiles. However, the direction and relative strength of the change for all food groups and nearly all nutrients are the same in both studies. The overall similarities in the results from these two large, nationally based studies provide convincing evidence that certain dietary patterns are consistently associated with a low percentage of kilocalories from fat in the American diet.

One of our initial purposes in conducting this research was to determine differences in correlations and dietary patterns associated with percentage of kilocalories from fat by demographic factors such as age, sex, race, education, and income. Surprisingly, we found few differences. While absolute intake of nutrients and foods did vary by demographics, relative intake, as expressed by our ratios in Tables 3 and 5, varied little by age and sex. Although nutritionists can conceive of many food group intake patterns low or high in percentage of kilocalories from fat, perhaps few distinct patterns actually exist. A possible reason for the few subgroup differences found here is that our short list of food items did not allow variability in dietary patterns to emerge.

In our data, percentage of kilocalories from fat was substantially lower in Hispanics. Our questionnaire, however, has not been compared with dietary records or recalls in this subgroup. In fact, many foods typical for Hispanic subgroups are not included on the questionnaire because such foods do not greatly contribute to total nutrient intake in the US population. In addition, reported intake of nearly all 59 food items was higher among Hispanics than among Blacks and Whites (L. C. Harlan, written communication, January 1993). These considerations, along with the smaller overall numbers of Hispanics, make the data for this important subgroup less trustworthy than those for other racial/ethnic groups, and further research is needed.

Our data show that Americans, on average, continue to consume a diet considered to be too high in fat (mean of 38.8% of kilocalories). Only in the lowest quartile did median values for percentage of kilocalories from fat ap-

proach the recommended level of 30% or less. However, individuals in the lowest relative to the highest quartile appeared to have dietary patterns most consistent with dietary guidelines both from a nutrient and food group perspective. This general finding is consistent with reported intakes of Americans adhering to a low-cholesterol diet in the NHANES II data[24] and among free-living families in Finland.[25] Nutrients of concern (e.g., iron and calcium) frequently found in higher fat foods appeared to be consumed in similar quantities by individuals in each quartile. Although it can be argued that many individuals should be consuming more of these nutrients, the present data suggest that lowering the percentage of kilocalories from fat may not necessarily decrease absolute intake of these important nutrients. As expected, absolute intakes of fatty acids and cholesterol were all lower in the lowest quartile, a generally positive outcome from a public health viewpoint. Vitamin E, however, was also lower, and this nutrient may play a role in both cancer and cardiovascular disease prevention.[26,27] Zinc and magnesium are reported to decline with decreasing fat intake[8]; however, because these minerals were not included on our database, we could not evaluate this possibility. This area of concern should be explored further as low-fat diets are recommended to the population.

It is clear from our data that individuals with a low percentage of kilocalories from fat tend to have dietary patterns notably higher in vitamin C and moderately higher in folate, dietary fiber, and carotene. All of these dietary constituents are being investigated for their role in reducing cancer risk. Our data show that when intakes of fat or nutrients/food groups are investigated, important concurrent dietary factors come into play and must be evaluated. Percentage of kilocalories from fat is highly correlated with certain nutrients and food groups but only weakly associated with others. One cannot be sure, therefore, whether an effect found for lower percentage intakes of kilocalories from fat is really due to higher intakes of vitamin C or folate unless each of these factors is independently evaluated. Assessing total diet is an important factor in sorting out diet and disease relationships.

Another important public health issue involves considering alcoholic beverage intake in studies assessing fat and chronic disease associations. Many heavy drinkers have low intakes of both total fat and percentage of kilocalories from fat and are thus placed in the "healthiest" dietary group, possibly obscuring important findings regarding diet and chronic disease risk. Recommendations for alcohol intake suggest moderation[1-6]; however, from a public health viewpoint, recommending a level of 30% of kilocalories or less for fat still leaves questions regarding how to account for alcohol kilocalories in reducing percentage of kilocalories from fat.

Individuals generally choose to eat foods and not nutrients, and food is selected in the context of a total diet and life-style. We have shown that a single important public health concern, percentage of kilocalories from fat, consistently correlates with selected food groups and nutrients. Individuals with diets low vs high in percentage of kilocalories from fat generally appear to most closely meet current dietary guidelines[6] (an exception is heavy alcohol consumers). The extensive and expensive dietary counseling among motivated women in diet trials[7,8] achieved diets generally lower in percentage of kilocalories from fat than are found in the US population. This approach, however, is not realistic from a public health perspective. Dietary guidelines should advocate a simple food message of increasing intake of fruits, vegetables, whole grains, and low-fat dairy products in a low-fat context. This positive message may not only increase the intake of nutrients/foods that might protect against chronic disease but may also reduce energy intake from fat. □

Nominations Solicited for Environmental Health Award

The American Academy of Sanitarians is requesting nominations for the 12th annual Davis Calvin Wagner Award. The award, to be presented at the Academy Luncheon during the annual Educational Conference of the National Environmental Health Association, will consist of a plaque and a $500 honorarium. The award is open to all Diplomates of the Academy. Qualifications include the following:

1. The award recipient exhibits resourcefulness and dedication in promoting the improvement of the public's health through application of environmental health and public health practices.
2. The award recipient demonstrates professional, administrative, and technical skill and competence in raising the level of environmental health.
3. The recipient continues to improve him- or herself through involvement in continuing education programs to keep abreast of new developments in environmental health and public health.
4. The recipient is of such excellence as to merit Academy recognition.

Nomination for the award may be made by a colleague or a supervisor and must include the following: name, title, grade, and current place of employment; a description of the nominee's educational background and professional experience; a narrative statement of how the person meets the criteria for the award, including a description of specific accomplishments and contributions on which the nomination is based; and three endorsements (an immediate supervisor and two other members of the professional staff or other persons as appropriate).

The deadline for receipt of nominations is *April 15, 1994.* Three copies of the nomination must be submitted and should be sent to Dr John G. Todd, Chairman, Davis Calvin Wagner Award, 17309 Fletchall St, Poolesville, MD 20837.

The Geographic Variation of Cancer Incidence in Ontario

Stephen D. Walter, PhD, Susan E. Birnie, MBA, Loraine D. Marrett, PhD, S. Martin Taylor, PhD, Donna Reynolds, MSc, John Davies, PhD, John J. Drake, PhD, and Michael Hayes, PhD

ABSTRACT

Objectives. Our objectives were (1) to describe an analysis of the spatial pattern of cancer incidence in Ontario and (2) to discuss the quality of data in the Ontario Cancer Registry with respect to the accuracy of local cancer rates.

Methods. Cancer incidence rates were calculated for 22 cancer sites in 49 counties of Ontario during 1976 to 1986. Capture–recapture methods were used to estimate completeness of case registration, and completeness of residence information was also assessed. Spatial autocorrelation was used in measuring the geographic pattern of incidence rates. Comparisons were also made between sexes and with earlier data from 1966 to 1975.

Results. The quality of the geographic data in the registry appeared good, and corrections for incomplete or inaccurate registration had little impact. About one third of the sex–site combinations showed some evidence of spatial patterning in the cancer rate. Particularly strong regional variation was noted for cancers of the stomach, lung, uterus, and prostate.

Conclusions. The analysis revealed a number of cancers with significant spatial patterning of risk. Further work is needed to relate the cancer data to other information on potential life-style and environmental factors. (*Am J Public Health.* 1994;84:367–376)

Introduction

Cancer is a leading cause of morbidity and mortality in most parts of the world. In Ontario, approximately 34 000 cases are diagnosed annually, and the lifetime cumulative risk of cancer is about 31% for men and 25% for women.[1] One way to investigate the possible impact of environmental factors is through ecologic analysis of spatial and temporal patterns of cancer incidence at the international, national, or regional level.[2–10] Many recent cancer atlases have been used for this purpose,[11] and some studies[12,13] have used formal statistical analyses of the spatial pattern.

The present study examined the pattern of cancer incidence in Ontario to determine whether regions with high cancer risk were spatially aggregated and whether the spatial pattern has persisted over time. The quality of the available data was assessed with respect to the accuracy of local cancer rates.

Methods

Indirectly standardized incidence ratios were calculated for each of 22 cancer sites by sex for each of the 49 provincial counties during 1966 to 1975 and 1976 to 1986, by using Ontario rates as the standard; coefficients of variation over counties were also calculated. Also, the world standard population was used to calculate directly standardized incidence rates for the entire province.

Quality of Data

Cancer incidence data for the periods of study were obtained from the Ontario Cancer Registry, which covers the entire provincial population of 9.1 million (1986 census). Case information was derived from hospital discharges, pathology and regional cancer center reports, and death certificates. Annually, more than 200 000 such records with a mention of cancer are processed. Computerized record linkage and medical logic systems are used to bring together the data on each individual.[14]

Two issues of data quality arise that are relevant to the examination of regional variation in incidence: (1) completeness and accuracy of case registration and (2) completeness and accuracy of residence information. Previous work has shown that accuracy of case registration in Ontario is good, with a high proportion of histologically confirmed cases.[14]

Completeness of Case Registration

The overall completeness of case registration for 1982 was estimated at 95% by means of capture–recapture methodology.[15] The same method was applied here to each site–sex combination to estimate county-level complete-

Leukemia (204–208)	M	6 097	11.90	.27	94.7	5 941 (97.4)
	F	4 682	7.62	.43	93.7	4 531 (96.8)

Note. ICD-9 = *International Classification of Diseases*, 9th version. M = male; F = female. Rates are per 100 000.

ness. Log-linear models were fitted[16] with record source types, counties, and their interactions as independent variables. The percentage of missing cases and the corresponding completeness rates were estimated for each county. "Corrected" standardized incidence ratios were calculated after addition of the estimated missing cases to the reported cases.

Comparisons of the uncorrected and corrected standardized incidence ratios indicate the effect (if any) of incompleteness on spatial patterns. The corrected data were adopted unless there was a relatively high negative correlation between the completeness rate and the uncorrected standardized incidence ratio; this might indicate an artificially enhanced spatial pattern in the corrected rates caused by the correction itself.

Completeness of Residence Information

About 3% of cases lack residence information at the county level.[17] There is substantial variation by site, depending largely on the types and numbers of source records contained in the registry, from about 1% for cancers with high hospitalization and case-fatality rates (e.g., lung and pancreas) to about 15% for cancers commonly registered only by pathology reports, which often lack residence information (e.g., melanoma).

In order to use the cases with unknown residence, the geographic referral pattern for each hospital was used to assign residences on a proportional basis. For each hospital, incident cases involving a known residence were used to estimate the proportion of patients from each county. The cases at each hospital involving an unknown residence were then assigned to counties in the same proportions. The final case frequency for each county was derived by summing allocations across hospitals and adding them to the cases involving a known residence.

Accuracy of Residence Information

The concordance of county of residence information within 1 year of diagnosis was examined for patients with multiple records. The coded county of residence, as used in the spatial analysis (normally from the earliest source record after diagnosis), was compared with that from up to five later source records.

Statistical Methods

Spatial analysis of incidence rates. Two methods were used to measure spatial aggregation of the county standardized incidence ratios. Moran's I is a correlation-type index based on continuous data values.[18] The nonparametric rank adjacency statistic D is calculated as the average absolute difference in ranks over pairs of adjacent counties.[19] High values of I and small values of D indicate spatial aggregation (i.e., the tendency for similar rates to be geographically clustered).

Significance levels for I are based on approximate normal z statistics; for D, they must be established through simulation.[19] One-sided significance tests were adopted; two-sided tests are inappropriate since negative autocorrelation would require a "checkerboard" adjacency pattern of high and low rates that would not be plausible for reasonable environmental hypotheses.

Other simulations evaluating the power of these two methods have used various patterns that might result from environmental effects.[20] The power for I was generally high. However, D was also calculated for comparability with previous work elsewhere[12,13]; its power was generally satisfactory, except for certain spatial patterns involving risk elevation in a small number of counties.[20]

I and D were calculated for the completeness rates and the uncorrected and corrected standardized incidence ratios. The ratio I/I_{max} was also calculated, where I_{max} is the maximum attainable value of I in a particular set of data.[18] The computation of I requires a weighting matrix to represent the spatial contact or distance between all possible pairs of counties. In our full set of analyses, a variety of weights was used to represent plausible environmental patterns.[19] For simplicity, we present detailed results only for the simple binary weights indicating adjacency or nonadjacency of county pairs; results with the other weight functions were usually very similar and will be mentioned only in the case of substantial discrepancies.

In determining the strength of clustering in the data, we relied primarily on I as a formal measure of overall spatial aggregation. The mapped data were also visually assessed as a secondary strategy in the identification of high-risk areas. Experimental evidence indicates modest agreement between the visual and statistical methods of data interpretation, although the eye sometimes reacts in unpredictable ways to the way in which data are displayed.[21]

Correlations between sexes, between sites, and over time. The correlations of the county standardized incidence ratios between sexes and between sites within sexes were calculated for the 1976 to 1986 data. Correlations of the county standardized incidence ratios for 1966 to 1975 and 1976 to 1986 for each site and sex were used to examine temporal persistence in spatial patterns; owing to some boundary changes, a few counties had to be combined in this analysis for compatibility over time, resulting in 46 areal units.

Results

The number of cases by site ranged from just over 400 (female lip cancer, rate = 0.55) to 41 880 (breast cancer, rate = 68.7) (Table 1). The coefficients of variation for the uncorrected standardized incidence ratios varied from ratios .01 for breast cancer to .58 for female lip cancer.

Completeness of Case Registration

Table 1 shows that lip and bone cancers and female melanoma had relatively low completeness of registration (<90%). Moderate completeness rates (90% to 95%) were found for colon cancer in both sexes, stomach and uterine cancer in females, and melanoma and prostate and bladder cancer in males. For six sites, the estimated completeness slightly exceeded 100%. This could be due to small sample sizes, dependence between the data sources, or unrecognized duplicate registration. Most sites had very limited geographic variation in completeness of registration.

Completeness of Residence Information

For most cancer sites, more than 95% of registered cases involved a known county of residence (Table 1). For melanoma and lip cancer, which had lower completeness rates, hospital referral patterns were used to make assignments for missing residences. This adjustment had almost no impact on the subsequent spatial analysis. Accordingly, only cases involving a known residence were used for the final analyses of spatial pattern.

Accuracy of Residence Information

The concordance between the residences listed on the diagnosis record and subsequent records was generally high. For example, among patients with at least two records in the registry, the agreement between the diagnosis record and the next source record was 97% for stomach cancer and 94% for lung cancer; even for cancer of the cervix, one of the least reliable sites, the figure was 91%.

Spatial Analysis

General findings. Significance tests based on I and D were usually consistent, and the results found with uncorrected and corrected standardized incidence ratios were similar. Correlations between the uncorrected standardized incidence ratio and the completeness rate were usually small.

No spatial aggregation was found, for either sex, for cancers of the gallbladder, bladder, brain, and thyroid; non-Hodgkin's lymphoma; Hodgkin's disease; or leukemia (Table 2). Also, there was no aggregation for female breast and ovarian cancers. The remaining sites did exhibit spatial aggregation for at least one sex, as discussed below.

Lip cancer. The male data exhibited some spatial aggregation through significant I values and a fairly high I/I_{max}. D was close to significance. There were localized pockets of high and low rates. High rates occurred in certain central and northeastern areas, while rates were low in the urban areas bordering Lake Ontario (Figure 1). Although the completeness rates were relatively low and spatially structured (high completeness rates around Toronto and lower rates in the east and north), their correlation with the standardized incidence ratios was essentially nil. A strong correlation between the two time periods suggests persistence of the spatial pattern.

For females, no strong spatial pattern was evident, but there was a fairly high correlation with the male data. Analyses with some of the alternative weights were significant, but the I/I_{max} values were low. The female spatial pattern may be attenuated by the small numbers of cases, relatively low completeness of registration, and moderate correlation between the uncorrected standardized incidence ratios and completeness rates.

Esophageal cancer. There was weak spatial aggregation in males, with a dispersed pattern of high rates in the north and low rates in some central counties. However, I/I_{max} was not large, and variable significance was found when alternative weights were used. The correlation over time was moderate, but there was almost no correlation between sexes. The negative correlation of completeness rates with the uncorrected standardized incidence ratios may have spuriously enhanced the spatial pattern in the corrected rates. There was no evidence of spatial aggregation in females.

Stomach cancer. Strong spatial aggregation was apparent in both sexes. Northern Ontario and some areas near Lake Ontario had high rates, while central Ontario had lower rates (Figure

*$P < .05$; **$P < .01$.

2). Significant spatial patterns were found for almost all of the alternative weighting matrices. I/I_{max} values were generally high. Correlations between the sexes and over time were both high.

Colon and rectal cancer. These sites were examined jointly because of the potential for cross classification. However, the correlation of county rates for the two sites was low in both sexes (−.09 in males, −.15 in females), suggesting that systematic errors are unlikely to have influenced the geographic patterns.

Significant spatial patterns were found for both sites in females, with persistence over time. For colon cancer, there were groups of counties with high rates in the northeast and central areas and groups with low rates in the far north and west of Lake Ontario (Figure 3). Most of the alternative weighting matrices for I gave significance, but I/I_{max} values tended to be low. The low geographic variation in incidence may limit the power to detect a spatial pattern for this site.

The spatial aggregation was weaker for rectal cancers in females. Higher rates were more common in the north and near Georgian Bay, and low rates occurred in east-central Ontario and near Lake Erie. Geographic variation in rates was low. Significance in I occurred only with the binary weights. The high negative correlation between the uncorrected standardized incidence ratio and the completeness rate suggests the possibility of an artifact in the spatial pattern of the corrected standardized incidence ratios. However, similar results were found in both the corrected and uncorrected data, indicating a minimal effect of the correction on the analysis.

Pancreatic cancer. Male rates were spatially clustered, with high rates in the north, but no pattern was found for females. Moderate correlation was observed between the sexes, and there was a modest correlation over time in males.

Lung cancer. There were strong geographic patterns for both sexes, with high correlations between sexes and over time. High rates were found in large areas of the northeast and east and in some counties near Lake Ontario and in the southwest (Figure 4). I/I_{max} was generally high.

Bone cancer. While the male data did not demonstrate a spatial pattern, female rates appeared to cluster in small pockets of high and low rates. For females, high rates were found in areas of eastern Ontario and counties bordering Lake Erie. Low rates were found near Lake Ontario. The pattern yielded only a modest value of I, the significance of which did not persist using the alternative weights. There was a weak correlation over time. The small sample size and relatively low completeness of registration may be partly responsible for the inconsistent findings.

Malignant melanoma of the skin. Female rates showed a significant clustering, with a high I/I_{max} value and an elevated risk in a group of counties west and north of Toronto (Figure 5). Rates for males gave some visual impression of a north–south gradient with higher rates in the south, but only one weight matrix for I gave significance. The stronger significance of clustering in females is probably related to the more frequent

contiguity of high-risk counties in the south–central area in comparison with the somewhat less structured pattern for males. Evidence for persistence over time was lacking for both sexes, but the correlation between sexes was relatively high.

Cervical cancer. There was a weak and dispersed geographic pattern with strong persistence over time. High rates tended to occur in northern Ontario and around Georgian Bay, while rates in the southwest were generally low (Figure 6).

Corpus uteri cancer. A significant spatial pattern was seen, with persistence over time. Rates were low in northern Ontario and generally high in the southwest (Figure 7). The effect was dispersed, with large areas of high and low rates. The significant spatial pattern persisted for most of the weighting matrices, and I/I_{max} values were moderately high.

Prostatic cancer. There was strong spatial aggregation, with a high I/I_{max} ratio. A risk gradient by latitude, with low rates in the north and high rates in the southwest, was observed (Figure 8). However, there was a low correlation over time, suggesting a transient or recent effect.

Kidney cancer. The data for males exhibited weak spatial aggregation that did not persist over time. There were small clusters of high and low county rates; however, groups of high rates often adjoined low rates, complicating the overall picture. For females, the spatial pattern was even weaker.

Discussion

Quality of Registry Data

Overall, the quality of the geographic data in the provincial registry was found to be good. The methods used to adjust for incomplete registration and missing residence had little impact on the spatial analyses of the standardized incidence ratios.

Spatial Analysis

Overall, about one third of the sex–site combinations showed some evidence of spatial aggregation, with little difference in results using different weighting schemes. Many of the sites with significant spatial aggregation also evidenced persistence over time (e.g., cancer of the lip and esophagus in males; cancer of the colon, rectum, cervix, and uterus in females; and cancer of the stomach and lung in both sexes). While female thyroid and breast cancers showed no spatial aggregation, they did have a strong correlation over time. It may be that the risk factors for these sites are not spatially aggregated but nevertheless vary geographically.

Interpretation of Significant Spatial Patterns

We now discuss the findings for those cancer sites showing some evidence of spatial aggregation in relation to their major risk factors[22] (summarized in Table 3) and their distributions in Ontario.[23]

Lip cancer. Lip cancer occurs most often in males, among whom significant spatial aggregation and a strong correlation between time periods are apparent. There is also a correlation between sex-specific rates. Lip cancer is strongly associated with exposure to the sun and less so with smoking, particularly of pipes. High rates have been reported among sailors, fishermen, and farmers, presumably because of their solar exposure. In Ontario, the highest rates are found in areas where farming and other outdoor vocations, such as forestry, are common; low rates occur in the urban centers.

Gastrointestinal tract cancers. Several gastrointestinal sites show spatial aggregation in one or both sexes. In addition, there are strong correlations in the male data between stomach and esophageal cancer rates (.48), esophagus and pancreas cancers (.32), and stomach and pancreas cancers (.45).

The most important known risk factors for gastrointestinal cancers are dietary, although the relevant dietary

components vary by site; there are currently no regional data on food consumption patterns in Ontario. Other risk factors include socioeconomic status (SES) (low or high, depending on site), alcohol consumption, and smoking. While there are no regional data on cigarette consumption, there is information on the spatial distribution of SES indicators (e.g., incidence of low income or low education) from census data and of alcohol from regional sales data. It is not known whether SES is directly related to cancer or is a surrogate for some particular aspect of life-style or behavior (e.g., smoking). There is substantial international variation in the incidence of gastrointestinal cancers, and some of the geographic variation found in Ontario may reflect its ethnic diversity.

Esophageal cancer shows spatial clustering in men but not in women. It is associated with consumption of tobacco and alcohol and with low SES. Its pattern in men is generally similar to that for apparent consumption of alcohol. Those who both drink heavily and smoke heavily are at particularly high risk. There is a strong correlation between esophageal and lung cancers in men (.40), and the rate of lung cancer is likely to be a good proxy for smoking prevalence. Consumption of alcohol and tobacco is higher in men, which probably explains both the 3:1 male–female rate ratio and the stronger geographic pattern in men. The distribution of this cancer is similar to that of low education.

Stomach cancer shows the strongest evidence for spatial aggregation and involves strong correlations between sexes and over time. Stomach cancer is particularly interesting because of its consistent temporal decline, its substantial international variation, and its persistence of risk in migrants. Its development is probably related to low intake of fresh fruits and vegetables, high intake of nitrates and nitrites, and low SES. Its pattern in Ontario is similar to that for low education. The strong correlations of stomach cancer with esophageal cancer in males (.48) and with lung cancer in both sexes (.56 and .34 in males and females, respectively) may partly reflect the fact that all of these cancers are more common in people of lower SES. Likewise, a negative correlation with colon cancer in females (−.33) may reflect colon cancer's association with higher SES. The fact that some of these correlations are sex specific implies that SES may be an indicator of different factors in the different cancer sites (e.g., for stomach cancer, it may be a surrogate for a high-risk diet; for lung cancer, it may indicate smoking status).

Cancers of the colon and rectum cluster in females only, although there is a moderate correlation between sexes and persistence over time in females only. These two cancers are not correlated with each other; however, there is a moderate correlation between rectal cancer and lung cancer in both sexes (.28 and .30 in males and females, respectively). Colo-rectal cancers are believed to be related to high levels of fat and low levels of fiber consumption, although the data are less consistent for rectal cancer. Rectal cancer may also be related to intake of alcohol, and its pattern appears similar to that for alcohol sales in Ontario. The pattern of colon cancer is roughly inverse to that for low education; conversely, rectal cancer is distributed similarly to low levels of education.

Cancer of the pancreas, which appears to cluster in males but not females, is associated with cigarette smoking. In males, there is a moderate correlation between rates for pancreas and lung cancers (.27), which suggests that geographic aggregation in pancreas cancer may be related to variation in smoking rates. Pancreatic cancer may also be related to diet, but studies have produced conflicting results regarding particular dietary constituents. Its correlations with esophagus (.32) and stomach cancer (.45) in males suggest the possibility of common risk factors.

Lung cancer. Lung cancer shows strong spatial aggregation in both sexes, with a strong correlation between sexes and over time. It is well known to be strongly associated with tobacco con-

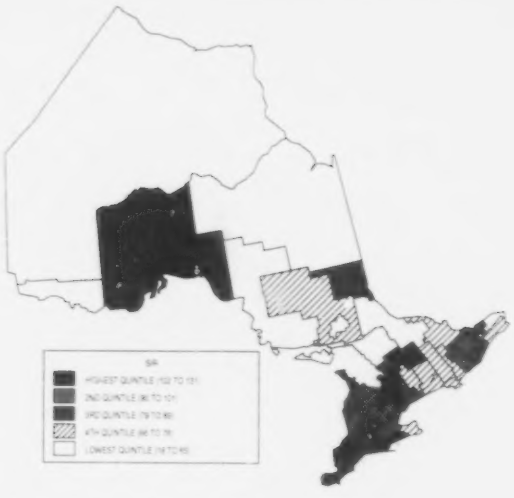

FIGURE 5—Standardized incidence ratios (SIRs) by county, Ontario, 1976 through 1986: female melanoma.

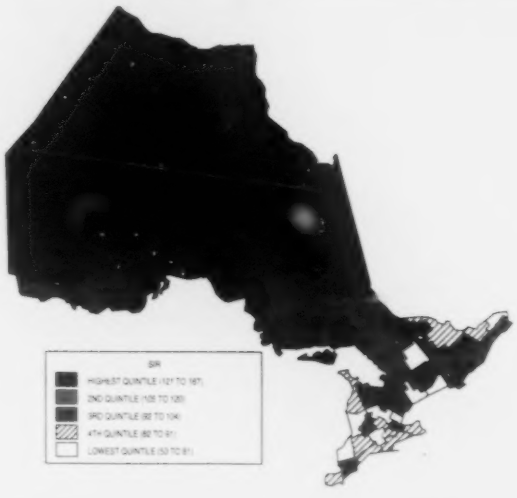

FIGURE 6—Standardized incidence ratios (SIRs) by county, Ontario, 1976 through 1986: cervical cancer.

sumption, but it is also more common in lower SES groups, and some cases are associated with occupational exposures to inhaled carcinogens such as asbestos, radon, and nickel dust. An analysis of Ontario lung cancer mortality found positive associations with employment in mining and prevalence of low education and a negative association with agricultural activity.[24]

Bone cancer. Bone cancer shows aggregation in females only, with a negative correlation between time periods. Although this is a relatively rare cancer, it is one of the most common tumors of adolescence. Except for ionizing radiation, little is known about its risk factors. It is interesting that one cluster of high rates occurs in the specialized agricultural areas bordering Lake Erie and the southern shore of Lake Ontario, where tender fruits and tobacco are grown.

Malignant melanoma of the skin. Melanoma shows a strong spatial pattern in females, with a moderate correlation between the sexes and no persistence over time. Its incidence is correlated with cancers of the corpus uteri (.56) and prostate (.44), possibly through common socioeconomic effects. Its incidence has been increasing rapidly in Ontario and in other light-skinned populations. Major risk factors include exposure to ultraviolet radiation, fair pigmentation, and high SES. Rates are higher in the southern part of the province, where solar ultraviolet radiation is most intense. However, the areas with the highest rates are those where cottaging or farming are common and exposure to solar ultraviolet radiation is presumably high. Melanoma rates show a weaker relationship to farming areas in males. In general, groups of people with high cumulative ultraviolet exposure (such as farmers) have a lower risk of melanoma than indoor workers. The male–female difference might therefore be related to some protective effect afforded by a higher chronic exposure level in males. Areas with the highest rates of melanoma are also those with the greatest proportions of people of British or German ethnicity, who are likely to be of fairer complexion. A recent study in Ontario indicated a risk associated with the use of sunbeds and sunlamps,[25] but the contribution of this factor to the geographic distribution is not known.

Genitourinary cancers. Cancers of the cervix and corpus uteri both show spatial clustering. The two sites have a moderate negative correlation (−.21), and their geographic patterns appear to be very different. As would be expected from its known associations with smoking, cervical cancer is positively correlated with lung (.32) and bladder (.34) cancers. In addition, its pattern is similar to that for prevalence of low education. There are no regional data available concerning sexual factors (e.g., age at first coitus or prevalence of venereal agents such as human papilloma viruses). Cervical cancer incidence has been declining in Ontario, at least in part because of screening. It is likely that there is geographic variation in screening intensity, although no such data are currently available.

Risk factors for uterine and cervical cancers are very different. Corpus uteri cancer is a hormone-dependent tumor resulting from high levels of unopposed estrogenic stimulation. It is primarily a disease of postmenopausal women who either are obese or have used replacement estrogen therapy during or after menopause. Nulliparous women are also at increased risk. Use of combination oral contraceptives, which guarantee exposure to progesterone along with estrogen, appears to reduce risk. In Ontario, the incidence of uterine cancer is correlated with that for melanoma and breast cancer, two other cancers associated with higher SES. There are no data available to examine regional variation in rates of obesity, nulliparity, or estrogen use, but the distribution of this cancer is roughly inverse to that for low education and low income.

The prostate is the second most common cancer site in males (after lung cancer), and it is strongly spatially aggregated. However, there is no evi-

TABLE 3—Major Known Risk Factors for Cancer Sites/Types with Evidence of Spatial Aggregation

Site/Type	Risk Factor(s)
Lip	Sunlight, tobacco
Esophagus	Tobacco, alcohol, diet low in fresh fruits and vegetables, low socioeconomic status
Stomach	Diet low in fresh fruits and vegetables, high intake of nitrates/nitrites (e.g., in water and preserved foods), low socioeconomic status
Colon/rectum	Diet high in fat, diet low in the fiber, high socioeconomic status (colon)
Pancreas	Tobacco
Lung	Tobacco, occupational exposures (radon, asbestos, etc.), low socioeconomic status
Bone	Ionizing radiation
Malignant melanoma	Ultraviolet radiation, susceptible phenotype (fair hair/eyes/skin), high socioeconomic status
Cervix uteri	Tobacco, sexual promiscuity (early age at coitus, multiple sex partners), viruses (human papilloma virus, herpes simplex virus type 2), low socioeconomic status
Corpus uteri	High levels of unopposed endogenous estrogens, use of exogenous estrogens (unopposed), use of combination oral contraceptives (protective factor), high socioeconomic status
Prostate	Diet (possibly high in fat), high levels of androgens
Kidney	Tobacco, obesity

dence of persistence of the spatial distribution over time. In our data, prostate cancer incidence is negatively correlated with esophageal and stomach cancers (−.47 and −.30, respectively), again possibly as a result of socioeconomic effects. There is substantial racial and international variation in the rate of prostatic cancer: US Blacks have the highest incidence, while Asian populations have very low rates. Upon migration to the United States, however, Asians' rates increase.

Little is known about the etiology of this cancer; the effects of dietary fat and male hormones are still speculative. Smoking may slightly increase risk, perhaps through its effect on male hormones.[26] There is a known high prevalence of latent tumors in asymptomatic older men. These tumors are sometimes detected during transurethral resection of the prostate for the treatment of benign prostate disease, which may partly explain why incidence is increasing but mortality is not.

In Ontario, the spatial pattern appears to be inverse to that for low education and is dissimilar to the pattern observed for mortality rates.[23] Thus, regional variation in disease detection rates may be a determinant of the incidence pattern. Examination of the incidence of this tumor in men under the age of 65, who would be less likely to receive transurethral resection of the prostate or general screening, may be informative. Completeness rates for registration of prostatic cancer were significantly spatially aggregated and were positively correlated with the uncorrected standardized incidence ratios; this would tend to have obscured a spatial pattern in the corrected standard-

ized incidence ratios, so the apparently strong pattern is not likely to be an artifact of variation in registration rates.

Kidney cancer shows weak clustering in males. Its incidence is correlated with that of esophageal, stomach, pancreas, and lung cancers, particularly in males. All of these sites except the stomach have been consistently associated with tobacco consumption (the strongest known risk factor), and most are common in lower SES groups. While obesity increases risk, the role of fat consumption and use of certain medications is uncertain.

Implications for Future Study

Several cancer sites have been shown to have significant regional variation in Ontario. The explanation for the variability, however, requires further study, especially concerning the possible impact of environmental factors. In related research to create an inventory of existing data sources in the province, a provincewide health survey and seven atmospheric, five hydrologic, one geologic, four land-use, two sociodemographic, and nine industrialization databases were identified as being potentially useful for ecologic studies.[27] The health survey, in particular, will provide regional data on many risk factors of interest: the 1990 Ontario Health Survey used a regionally stratified sample of about 47 000 Ontario residents and included questions concerning smoking, health behavior, diet, beverage consumption, occupation, and socioeconomic factors. Previous work on cancer mortality in Ontario[24] has revealed substantial variation between counties with respect to ethnic, industrial, and SES characteristics in censal data.

Ecologic studies of the kind described here provide a relatively inexpensive way of examining regional variation in health in large populations. The effects of environmental factors can also often be addressed by access to existing data sets.[28,29] However, these studies involve interpretational problems arising from the aggregated form of the data and effects such as variation in the size of the regional populations, migration, and disease latency.[19,28,29]

The census divisions of Ontario are quite variable in population size and area. However, the regional data values used in our spatial analyses were all given equal weight, so one needs to be less concerned about the possibly dominant effects of the large cities (here, notably, Toronto). Isodemographic map projections have been proposed to eliminate problems associated with heterogeneous population density. We decided against this option when mapping our data because the Ontario map becomes physically unrecognizable when this projection method is used; furthermore, one loses the information on the relative distance between regions, and physical distance is a more important determinant of interregional correlations than is population density.

Migration and latency are more difficult problems. The exposures relevant to cancer risk probably occur 10 to 20 years before diagnosis; thus, current residence will be an imperfect marker. Our use of incidence data eliminates any potential bias associated with postdiagnostic migration. Any bias due to prediagnostic migration of future cancer cases would most likely be evidenced by a relative cancer excess in urban areas near major treatment centers. Census data[30] indicate that 16% of the Ontario population in 1986 had moved from another census division since 1981, with relatively small differences in this rate across the province; this suggests that migration bias is unimportant. Furthermore, the spatial patterns observed in the incidence data are not compatible with an effect of this kind. We conclude that migration in the Ontario population is more likely to attenuate an environmental effect than to create bias.

With its large population, interesting regional patterns of cancer incidence, and known variation in risk factors for some cancers, Ontario appears to be a suitable location for further study of the relationship between environment and cancer. Future research might use the ecologic approach to relate cancer incidence and relevant "exposures" or adopt case–control and other designs with individually based data. □

Acknowledgments

This study was supported by a grant from the Ontario Ministry of Health. S. D. Walter holds a National Health Scientist Award from the National Health Research and Development Program, Health and Welfare Canada.

Using CD4 Counts to Evaluate the Stages and Epidemiology of HIV Infection in South Carolina Public Clinic Patients

Stephen Luby, MD, Jeffrey Jones, MD, MPH, and John Horan, MD, MPH

ABSTRACT

Objectives. CD4 lymphocyte counts decrease with the duration of human immunodeficiency virus (HIV) infection. We used CD4 counts collected for clinical reasons to evaluate the stage of HIV infection and the epidemiology of recent HIV infections among attendees of South Carolina's public health clinics.

Methods. We measured the CD4 T-lymphocyte counts of persons newly diagnosed with HIV infection April 1989 through June 1990 at South Carolina public health clinics who returned for follow-up.

Results. Of 812 newly diagnosed HIV-infected health department patients, 420 (52%) had their CD4 lymphocyte counts measured. Of these 420, 51 (12%) had CD4 counts of <200, the level below which prophylaxis for pneumocystis pneumonia prolongs survival, and 193 (46%) had CD4 counts of <500, the level below which zidovudine may prolong disease-free survival. The highest CD4 counts (≥ 900), which are associated with more recent HIV infection, were more common in females.

Conclusions. In South Carolina, almost half of newly reported HIV-infected persons who agreed to CD4 testing at the health department might benefit from immediate drug therapy. Within this population, women may be an emerging risk group that requires specifically directed HIV prevention efforts. (*Am J Public Health.* 1994;84:377–381)

Introduction

Several cohort studies demonstrated that CD4 lymphocyte counts decrease with the duration of human immunodeficiency virus (HIV) infection.[1–7] This decrease tends to be linear[8] and predicts opportunistic infection and progression to the acquired immunodeficiency syndrome (AIDS).[2–9] Thus, measuring the CD4 lymphocyte count of HIV-infected persons helps characterize the HIV/AIDS epidemic by staging HIV infection in a population. Indeed, CD4 counts could supplement HIV surveillance by characterizing groups with advanced HIV disease in need of drug therapy as well as identifying those persons most recently infected to evaluate changing demographics and risk groups for HIV transmission.

However, previous studies of CD4 counts in HIV-infected persons have been from restricted populations, including cohorts of homosexual men,[1,3,6,10,11] hemophiliacs,[2,12] attendees at two sexually transmitted disease clinics,[13] and members of the US Army,[14] which is 91% male and attempts to exclude persons who are homosexual, intravenous drug users, or HIV infected.

In March 1989, the South Carolina Department of Health and Environmental Control began offering CD4 lymphocyte testing free of charge at 81 clinics statewide to all HIV-infected persons reported to the health department. South Carolina law requires that all physicians, hospitals, and laboratories licensed by the state report persons with HIV infection to the Department of Health and Environmental Control.

Clinic nurses use these CD4 counts to identify persons who are late in the course of their HIV disease and therefore need immediate medical services. Persons with CD4 counts of <500 who are indigent qualify for Medicaid and are eligible to receive zidovudine through the federal drug reimbursement program. Persons with CD4 counts of <200 receive urgent medical referral to receive zidovudine and prophylaxis against *Pneumocystis carinii* pneumonia.

For this study, we retrospectively reviewed the CD4 lymphocyte counts of newly identified HIV-infected persons in the first 15 months of the South Carolina CD4 testing program. Our objectives were to determine the percentage and characteristics of HIV-infected persons who might benefit from drug therapy and to characterize the population of most recently infected persons.

Methods

Patients

We selected patients newly reported to the state's HIV registry April 1989 through June 1990 whose CD4 T-lymphocyte count was measured in the 90 days after their first positive HIV serology test. Hence, CD4 tests were

performed April 1989 through September 1990. A 90-day time frame was chosen to permit timely analysis of the data. We excluded HIV-infected children younger than 13 years old because their absolute CD4 counts are not directly comparable with adult CD4 counts.[15,16]

Specimen Handling

Nurses in the health department clinics collected blood samples from consenting HIV-infected patients. For patients originally identified in these health department clinics, CD4 lymphocyte counts were measured at the first posttest counseling session: that is, when the patient first learned of his or her HIV infection. All blood samples were analyzed by flow cytometry within 20 hours of being drawn with a Coulter Epics–Profile II flow cytometer (Coulter Corporation, Hialeah, Fl). Personnel in the South Carolina Department of Health and Environmental Control Bureau of Laboratories entered the absolute CD4 lymphocyte count (the product of the total lymphocyte count and the percentage of CD4+ lymphocytes) with the patient's name onto the state's mainframe computer, and the result was sent back to the originating clinic.

Data Analysis

The CD4 tests were matched by name, date of birth, county, and race with the Department of Health and Environmental Control surveillance registry of HIV-infected persons by one person working within the HIV/AIDS surveillance section of the department. For analysis we compiled a linked CD4 count/HIV registry microcomputer file with all personal identifiers removed.

We classified persons with absolute CD4 counts of ≥ 900 as recently infected and persons with CD4 counts of < 200 as having advanced HIV infection. We chose a count of 900 as a threshold for defining recent infection because previous researchers found 918 to be the average count for six uninfected control persons who were repeatedly tested.[17] A larger study has since found an average CD4 count of 890 among 63 repeatedly tested HIV-negative control subjects.[18] We chose CD4 counts of < 200 to indicate advanced infection because at this level persons have markedly increased risk of opportunistic infection.[9]

We initially evaluated age groups at the standard intervals used for the surveillance of HIV/AIDS—that is, ages 5–12 years, 13–19 years, and at 5-year intervals thereafter.[19] Because children under age 13 years were not analyzed, persons aged 13–19 comprised the youngest group analyzed. Because only 5% of the study population was in this youngest age group, we expanded the youngest category to include persons 20–24 years old to permit a more thorough statistical evaluation of age.

We calculated relative risks (RRs) and confidence intervals (CIs) by the method of Greenland and Robins using Epi Info software.[20] We used StatXact[21] software to perform significance testing of dichotomous outcomes by Fisher's exact chi-square association. Using Kwikstat software,[22] we compared mean ages across two groups by Student's *t* test and assessed the association between age and CD4 cell count using Pearson's correlation.

Results

Of the 1510 newly diagnosed HIV-infected persons more than 12 years old reported to the South Carolina Department of Health and Environmental Control April 1989 through June 1990, 812 (54%) were initially diagnosed as HIV infected at state clinics and 698 (46%) were reported from outside the state clinic system. Persons identified outside the state clinic system were significantly less likely to participate in the CD4 lymphocyte testing program compared with state clinic–identified patients (20% vs 52%; RR = 0.39, 95% CI = 0.33, 0.46) and were 1.9 times more likely to have CD4 counts of < 200 (23% vs 12%; RR = 1.9, 95% CI = 1.3, 2.9). Because persons diagnosed outside the clinic system were less completely represented in the database and because those non–public clinic patients who were tested appeared to overrepresent a selected group of persons with more advanced disease, we limited subsequent analysis to the 812 state clinic–identified patients.

Of these 812 newly reported HIV-infected patients, 420 (52%) had their CD4 lymphocyte counts measured at a state clinic within 90 days of their first positive HIV serology test. The mean age of clinic patients whose CD4 counts were measured was 30.7 years, which was similar to the mean of 30.2 years among HIV-infected clinic patients whose CD4 counts were not measured. Gender and urban or rural residence were not significantly associated with undergoing CD4 testing (Table 1). Whites were 1.4 times more likely than Blacks to participate in the lymphocyte testing program. Persons who reported no HIV risk factors were significantly less likely to undergo follow-up CD4 testing. No defined risk group for acquiring HIV infection was significantly more or less likely to be CD4 tested.

Within the study population of 420 newly diagnosed HIV-infected persons

[a]Two Hispanic persons are not included in the racial breakdown. Totals for racial groups differ slightly from those reported in Table 1 because five persons were recorded as a different race when they were HIV tested than they were during subsequent CD4 testing.

from state clinics, 51 (12%) had what we defined as advanced HIV disease (CD4 counts of <200). One hundred ninety-three persons (46%) had CD4 counts of <500. At the other end of the CD4 spectrum, 69 persons (16%) had CD4 counts of ≥900. The mean CD4 count for the population was 588 with a standard deviation of 347.

The distribution of CD4 counts by age, sex, race, location, and HIV risk factor is shown in Table 2. Females were 1.7 times more likely than males to have CD4 counts of ≥900 (95% CI = 1.1, 2.6). No significantly increased risks for recent infection were associated with age, race, urban versus rural residence, or risk group for acquiring HIV infection.

Reported risk factors for acquiring HIV infection for the 29 females who had CD4 counts of ≥900 are listed in Table 3. Among these 29 women, 21 (72%) reported heterosexual contact as their primary risk behavior for acquiring HIV infection. The proportional distribution of reported risk factors is not significantly different between females with CD4 counts of ≥900 and those with CD4 counts of <900.

At the other extreme of CD4 counts, persons more than 24 years old had a 15.2 times greater prevalence of advanced HIV disease than persons 24 years of age or younger (95% CI = 2.1, 108.7). Males were 1.8 times more likely than females to have advanced infection (95% CI = 0.9, 3.4). Persons who did not report an HIV risk factor were 2.4 times more likely to have CD4 counts of <200, but there were no other significant differences by HIV risk group, race, or urban versus rural location. There was no statistically significant Pearson correlation between age and CD4 count ($R^2 = 0.004$, $P = .18$).

TABLE 3—HIV Risk Factors for Females Whose CD4 Counts Were Tested, South Carolina, April 1989 through September 1990

HIV Risk Factor	Total	No. (%) with CD4 of ≥900
Heterosexual contact		
HIV-positive partner	31	7 (23)
Partner with HIV risk factors	14	4 (29)
Partner without known HIV risk factors	60	10 (17)
Intravenous drug use	13	5 (38)
No reported risk factor	8	3 (38)
Total	126	29

Note. χ^2 association; $P = .31$ for all factors.

Reanalysis of potential risk factors for recent HIV infection with absolute CD4 counts of 800 or 1000 as a cutoff for recent infection or 30 years as a cutoff for age did not substantially change the results.

Discussion

This study of CD4 lymphocyte counts among HIV-infected persons newly diagnosed in public health clinics in South Carolina found that 46% of tested persons had CD4 counts of <500,

the level below which zidovudine may improve disease-free survival.[23–25] This percentage corresponds with (1) the US Army estimate that 58% of their HIV-infected persons have CD4 counts of <500[14] and (2) the 50% of persons with newly diagnosed HIV infections in a Baltimore sexually transmitted disease clinic who had CD4 counts of <500.[13] Although none of these figures is generalizable to the HIV-infected US population, the figures provide evidence across different cohorts that a substantial proportion of HIV-infected persons have far enough advanced HIV disease to potentially benefit from pharmacologic therapy.

Although the majority of persons with HIV infection (even recent HIV infection) were male, a disproportionate number of more recent HIV infections occurred in females. This finding is consistent with other current data. The Centers for Disease Control reports that newly diagnosed cases of AIDS in females increased by 29% from 1988 to 1989 compared with an 18% increase for males.[26] St. Louis and colleagues recently reported US Job Corps data that noted a higher HIV seroprevalence among 16- and 17-year-old females than among males, which the authors suggest may reflect a recent increase in HIV infection in young women nationally.[27]

There are limitations to these results. First, CD4 lymphocyte counts are an imperfect measurement of the duration of HIV infection. There is considerable variability in the normal level of CD4 counts in uninfected persons[17,28] and in the rate of decline of CD4 counts among HIV-infected persons.[2,4] If different groups have different normal values or different rates of decline of CD4 counts, that could distort our extrapolation of the duration of infection from CD4 counts.

However, the limited data that are available suggest that CD4 counts in persons without HIV infection do not differ by gender or ethnicity,[18] and the only data on the effect of age on CD4 counts that we are aware of concern differences in young children, who were excluded from this evaluation. Indeed, if rates of decline of CD4 counts differed among different groups, the duration of infection would be extrapolated most accurately early in the course of the illness before differential rates of decline produced increasingly larger differences (CD4 count decline is linear in individuals with HIV infection[8]). Thus, our data on recently infected persons would be less susceptible to this potential distortion.

A second concern is that the apparent increased prevalence of recent infections in females could reflect their earlier use of health care. More recent infection among females would then reflect earlier diagnosis rather than a trend in disease transmission. However, we have no evidence that females were seeking health care earlier than males. Because the data abstraction methods used did not recover the type of program that a person was tested under, we cannot determine whether recently infected females were disproportionately identified through, for example, prenatal screening efforts, which are not equally accessed by men. We do know, however, that once identified, HIV-infected females were not significantly more likely than males to return within 90 days for follow-up CD4 testing. Continued surveillance of CD4 counts among HIV-infected persons will answer this question. If higher CD4 counts reflect increased rates of new infection among females, then the differences in CD4 counts between the sexes will narrow as the relative numbers of infected females and males stabilize.

A third study limitation is that the study population is not representative of the entire HIV-infected population in South Carolina and so the results may not be generalizable. It included only persons who attended public health clinics and so likely underrepresents higher socioeconomic groups. Further, Blacks and persons who reported no risk factor for HIV transmission were less likely to have follow-up CD4 testing, which could permit an unmeasured selection bias that might affect our findings. Nevertheless, this study population is more diverse than previously reported study populations and so offers the opportunity for a more complete comparison of CD4 counts across age, sex, and HIV risk groups than was previously available.

In conclusion, CD4 counts reflect the duration of HIV infection and so can enhance the characterization of HIV disease in a population. In South Carolina, among HIV-infected persons newly reported to the health department who agreed to CD4 lymphocyte testing, 46% might benefit from immediate drug therapy. Within this study population females may represent an emerging risk group that requires specifically directed HIV prevention efforts. □

The Trading of Sex for Drugs or Money and HIV Seropositivity among Female Intravenous Drug Users

Jacquie Astemborski, MHS, David Vlahov, PhD, Dora Warren, PhD, Liza Solomon, DrPH, and Kenrad E. Nelson, MD

ABSTRACT

Objectives. Data from 538 women in a cohort study recruited in 1988–1989 were analyzed to determine whether trading sex for drugs or money was independently associated with human immunodeficiency virus (HIV) seroprevalence in a population of female intravenous drug users.

Methods. The women were grouped according to the number of partners with whom they reported trading sex for drugs or money during the previous 10 years: none, 1 through 49 (low), or 50 or more (high); the prevalence of HIV seropositivity in the three groups was 23.2%, 23.7%, and 47.6%, respectively. Logistic regression was used to compare the low- and high-trade groups separately with the group that reported no trading.

Results. Low trading was not associated with seroprevalent HIV infection. In a multivariate model, high trading (compared with no trading) was significantly associated with HIV seropositivity after adjustment for cocaine use, history of sexually transmitted diseases, and duration of intravenous drug use.

Conclusions. These data indicate that, among intravenous drug–using women, high levels of trading sex for drugs or money were independently associated with HIV infection. This group needs to be targeted for further intensive intervention. (*Am J Public Health*. 1994; 84:382–387)

Introduction

Intravenous drug users are at increased risk for infection with the human immunodeficiency virus (HIV), owing primarily to the sharing of contaminated injection equipment.[1] Specific risk factors for seroprevalent HIV infection among intravenous drug users include high frequency of injection, use of shooting galleries, and cocaine injection.[2,3] Recent studies have found higher HIV seroincidence rates in female than male intravenous drug users,[4,5] which has led to the suggestion that sexual transmission is more important for women. The extent to which sexual transmission contributes to the occurrence of HIV infection among intravenous drug users has been difficult to demonstrate, with conflicting results across studies.[6–10] A national survey of female prostitutes found significantly higher rates of HIV infection among those who reported intravenous drug use,[11] suggesting that prostitution might be a means of obtaining money to support a drug habit and that the excess HIV infection in these women was probably related to injection behavior. The purpose of this study was to identify whether trading sex for money or drugs is associated with HIV infection among intravenous drug–using women, independent of drug injection practices.

Materials and Methods

Study Population

The organization and data collection methods for this study have been described elsewhere in detail.[12,13] In brief, intravenous drug users were recruited by word of mouth from a variety of community service agencies into a study (the AIDS Link to Intravenous Experiences [ALIVE] Study) of the natural history of HIV infection in a freestanding clinic between February 1988 and March 1989. Eligibility criteria included age older than 17 years, history of injecting drugs within the previous 10 years, and no history of an acquired immunodeficiency syndrome (AIDS)–defining illness at study entry.

Data Collection

After pretest counseling was performed and informed consent was obtained, serum was collected for HIV antibody assays and each participant was interviewed to obtain demographic information; medical history; drug use history, including injection practices, since 1977; and a 10-year history of sexual activity. Participants who reported injecting drugs were asked the last time they had injected. Then all were asked about the following behaviors in the 6 months prior to the last injection: frequency of injection, type of drug used, number of partners shared with, and attendance at shooting galleries. For this study, "current use" was defined as injection within the 6 months prior to interview. We asked all participants about duration of injection in years and then asked for a year-by-year history for the previous 10 years. For women, the 10- year sexual history included the total number of

different male sex partners, the number of male intravenous drug–using partners, and the number of males with whom sex was traded for drugs or money. In pilot studies, some women were put off by the term "prostitute" but not by the phrase "trading sex for money or drugs"; the latter phrase was adopted for the final instrument used in this study.

Serum samples were assayed for HIV-1 antibodies by enzyme-linked immunosorbent assay (ELISA; Genetic Systems, Seattle, Wash). Confirmation was by Western blot (DuPont Co, Wilmington, Del) techniques.

Data Analysis

Because the risk of HIV infection due to trading sex for drugs or money among women was of primary interest, the sample was restricted to those 538 women for whom this information was available. On the basis of a preliminary analysis, the women were grouped into three categories, according to the number of partners with whom they reported trading sex for drugs or money during the 10 years prior to interview: none, 1 through 49 (low), and 50 or more (high). The cutoff of 50 was chosen to achieve a minimum sample size for meaningful analysis.

For analyses, drug-use variables within the last 6 months were used because recall of specific injection practices was felt to be more accurate for the most recent period and drug injection practices have been shown to be relatively stable over time in this population.[2,3] Therefore, recent behavior combined with duration of injection (more than 5 years vs 5 years or less) were both incorporated into analyses as a means to adjust for drug injection practices when we examined the association of trading sex for drugs or money and HIV seropositivity.

The high and low traders were each compared in separate analyses with the nontraders to examine the association of trading with HIV seroprevalence. Categorical variables were first analyzed by means of odds ratios and chi-square statistics. Variables on univariate analysis that were significant at an alpha level of .05 or less were systematically examined with multiple logistic regression to assess the independent risk associated with each.[14] Variables were retained in the multivariate model if the variables significantly improved the fit of the model.

Results

Of the 552 female intravenous drug users recruited into the ALIVE study, we had complete data on the trading sex question for 538: 327 (60.8%) reported no trading, 169 (31.4%) traded with fewer than 50 partners, and 42 (7.8%) traded with 50 or more partners. The median number of male sex partners (including trading partners) in the previous 10 years for the no-, low-, and high-trade groups was 3, 8, and 400, respectively.

The prevalence of HIV seropositivity among the nontraders, low traders, and high traders was 23.2%, 23.7% and 47.6%, respectively (Table 1). Compared with the nontraders, the low traders were younger and were more likely to have had sex with more than two intravenous drug users, to have had a sexually transmitted disease, and to have used oral contraceptives. Low traders were more likely than intravenous drug users who did not trade to have shared needles and to have gone to shooting galleries within the 6 months prior to interview, but they were not significantly different from those who had never traded with respect to current injection drug use, frequency of injection, or intravenous use of cocaine.

High traders were more likely than nontraders to have had sex with more than two intravenous drug users, to have had a sexually transmitted disease, and to have used intravenous drugs for at least 5 years. High traders did not differ from nontraders with regard to frequency of current intravenous drug use, frequency of injection, intravenous cocaine use, or having shared needles, but they were more likely to have attended shooting galleries.

When the analysis was restricted to the low- and no-trade groups (Table 2), univariate analysis showed that having traded sex for drugs or money was not associated with HIV seropositivity. Factors associated with HIV seropositivity were being Black, having had sex with more than two intravenous drug users, history of drug treatment, having used intravenous drugs for 5 or more years, having used intravenous cocaine, and having shared needles with more than one partner. As Table 3 shows, factors independently associated with HIV seropositivity on multivariate analysis were being Black (odds ratio [OR] = 4.75), having had sex with more than two intravenous drug users (OR = 2.31), and having used intravenous cocaine (OR = 3.10).

When the analysis was restricted to the high- and no-trade groups (Table 4), univariate analysis showed having traded sex for drugs or money to be significantly associated with HIV seropositivity (OR = 3.00). Factors associated with

being HIV positive on univariate analysis were being Black, age less than 35 years, having had sex with more than two intravenous drug users, history of any sexually transmitted disease, having used drugs for at least 5 years, having injected drugs within the last 6 months, having injected drugs at least once per day, having used intravenous cocaine, and having shared needles with more than one partner. Lesbian and bisexual sex practices were examined and found not to be associated with HIV seropositivity (OR = 1.13). As Table 5 shows, factors independently associated with HIV seropositivity on multivariate analysis were having traded sex for drugs or money (OR = 2.99), history of any sexually transmitted disease (OR = 1.84), 5 or more years of intravenous drug use (OR = 1.87), and having used intravenous cocaine (OR = 3.54). Additional analyses using continuous rather than categorical exposure variables did not alter the primary association of interest (data not shown).

In the analysis that was restricted to the high- and low-trade groups, a high frequency of having traded sex for drugs or money was associated with HIV seropositivity (OR = 2.93). Other factors associated with being HIV seropositive on univariate analysis were having had sex with more than two intravenous drug users, having undergone drug treatment, having used intravenous drugs for at least 5 years, having been arrested in the last 10 years, and having used intravenous cocaine. On multivariate analysis, only having traded sex for drugs or money (high trade) and having had sex with more than two intravenous drug users were associated with HIV seropositivity. Additionally, there was an interaction between having traded sex and having had sex with two or more intravenous drug users. Within the low-trade subset, women who had had sex with more than two intravenous drug users had an odds ratio for HIV seropositivity of 3.74 (95% confidence interval [CI] = 1.74, 8.05) compared with those who had had sex with two or fewer intravenous drug users. Within the high-trade subset, women who had had sex with more than two intravenous drug users had an odds ratio for HIV seropositivity of 0.37 (95% CI = 0.08, 1.73) compared with those who had had sex with two or fewer intravenous drug users. When only women who reported having had sex with two or fewer intravenous drug users were considered, high traders had an odds ratio for HIV seropositivity of 12.83 (95% CI = 2.83, 58.30).

Discussion

The data presented here are consistent with earlier published reports noting that the exchange of sex for money or drugs is common among intravenous drug–using women.[15–22] In this study, nearly 40% of the women reported exchanging sex for drugs or money at least once in the previous 10 years.

A major finding was a significantly higher rate of HIV infection for high traders (≥ 50 partners) than for nontraders. This statistical association persisted after simultaneous adjustment for multiple confounders, including duration of drug injection, use of intravenous cocaine, and history of sexually transmitted diseases. A significant association of HIV infection and trading sex for money or drugs after adjustment for drug injection practices indicates that the relationship was probably not due to more frequent or riskier drug injection practices among the high traders. The fact that a history of sexually transmitted diseases was independently associated with HIV infection after drug injection variables were controlled is consistent with a role for sexual transmission of HIV infection in this population. The statistically significant association of HIV seropositivity and high trading after adjustment for history of sexually transmitted diseases indicates that there is an independent effect of frequent trading of sex for money or drugs— that the behavior of trading is risky irrespective of history of sexually transmitted disease.

An unexpected finding was that HIV seropositivity rates were similar between the low traders (1–49 partners) and the nontraders. Because the median number of sex trading partners in the low-trade group was five, and the total median number of sex partners (including trading partners) in the previous 10 years was similar between the two groups (three for the no- trade group and eight for the low-trade group), the groups might be considered relatively homogeneous with respect to number of sex partners. It is also conceivable that the question about trading sex for money or drugs might have been perceived differently by different study participants; for example, women who reported a low number of trading partners might have included instances where they injected with a partner immediately prior to sex, but other women might not have considered such instances, especially with a regular sex partner, to be an exchange of sex for drugs. Additional studies will need to form questions differently to explore semantic and actual variations.

In the analysis that was restricted to low traders and nontraders, HIV infec-

tion was significantly associated with being Black, having used intravenous cocaine, and having had sex with more than two male intravenous drug users. Although similar findings have been reported by others for injection drug users as a group,[2,3,8,23] the difference here is that these variables distinguished among subgroups of intravenous drug–using women who had similar HIV seroprevalence rates. The data suggest differing risk profiles within a single population drawn from the same city during the same calendar time. Higher rates of HIV seropositivity among racial/ethnic minorities have been observed in other studies and probably reflect differences in risk behaviors that are inadequately measured with current instruments.[24]

HIV seroprevalence was higher in the high-trade group than in the low-trade group. In the analysis of risk factors involving these two groups, a significant interaction term showed that having had sex with two or more male intravenous drug users was risky for the low-trade group but, paradoxically, was "protective" for the high-trade group. This finding is consistent with the interpretation that women in the high-trade group were probably less likely to know whether their sex partners were high-risk and therefore less likely to report them. In addition, high traders and low traders may associate with different networks of individuals within which the underlying seroprevalence rates differ. More detailed data, including type of prostitution and frequency of condom use, are needed to better disentangle the effects of drug injection and sexual transmission within different social networks.

Before firm conclusions are drawn, several study limitations should be acknowledged. Because the sample was composed of volunteers, the extent to which this study population is representative of intravenous drug users in Baltimore or elsewhere is unclear. Therefore, this relationship should be examined in other cities with varying seroprevalence rates. The cross-sectional design, although efficient, cannot distinguish risk factors from prevalence correlates; therefore, prevalence-incidence bias cannot be excluded. Additional prospective studies are needed to confirm and expand the findings reported here.

In conclusion, although early studies of intravenous drug users found that HIV seroprevalence was similar for men and women[2,25] and some investigators concluded that transmission of HIV infection among intravenous drug users was parenteral rather than sexual,[6,7] more recent studies have acknowledged a more prominent role of sexual transmission in this population.[8,9] Further support of the importance of sexual transmission is provided by studies of incident HIV infection among current and former intravenous drug users that have shown higher rates of HIV infection in women than in men.[4,5] Other investigators have found an association between crack use and HIV seroprevalence[26,27] that is thought to be mediated by increased sexual activity. This study contributes to the growing literature on risk factors for HIV infection among female intravenous drug users by identifying an independent risk associated with the practice of trading sex for money or drugs in this population. Multiple studies have found that although intravenous drug users have changed drug-using behaviors in response to the AIDS epidemic, progress in the prevention of sexual transmission among intravenous drug users has not kept pace.[28] The data presented here provide additional evidence to support redoubled efforts to intervene on the issue of sexual transmission of HIV infection in this vulnerable population. □

Changes in HIV-Related Information Sources, Instruction, Knowledge, and Behaviors among US High School Students, 1989 and 1990

ABSTRACT

Objectives. Few data have been available among adolescents to determine behavioral changes that may prevent human immunodeficiency virus (HIV) infection. This analysis examines changes in the prevalence of self-reported HIV-related information sources, instruction, knowledge, and behaviors among high school students in the United States.

Methods. Two independent, multistage national probability samples of students in grades 9 through 12 were surveyed in 1989 (n = 8098) and 1990 (n = 11 631) with self-administered, anonymous questionnaires that included similar items.

Results. Compared with students surveyed in 1989, a significantly greater proportion of students surveyed in 1990 had received HIV instruction in school. Significant decreases were found in the proportion of White and female students who reported having had sexual intercourse, in the proportion of White students reporting two or more lifetime sex partners, and in the proportion of 15- and 16-year-olds, White students, and female students who reported having had four or more lifetime sex partners. For both years, students who had a greater level of HIV knowledge were less likely to have had multiple lifetime sex partners or to have injected illicit drugs.

Conclusions. The findings suggest that school-based HIV education and knowledge may be contributing factors in reducing certain risk behaviors that can lead to HIV transmission among secondary school youth. (*Am J Public Health.* 1994;84:388–393)

Deborah Holtzman, PhD, Richard Lowry, MD, MS, Laura Kann, PhD, Janet L. Collins, PhD, and Lloyd J. Kolbe, PhD

Introduction

Since the latter half of the 1980s, schools throughout the United States have been offering education programs to teach adolescents about human immunodeficiency virus (HIV) infection. However, the effect of such programs on HIV-related knowledge and behaviors among adolescents is largely unknown. Several recent studies have investigated the extent to which adolescents in the United States engage in behaviors that place them at risk for HIV infection.[1–5] Although a few studies have tried to assess changes in these behaviors over time, their findings have been limited.[6–8]

To begin to evaluate the effect of national public health information and education efforts on HIV-related behaviors of US adolescents, we compared data from two national probability samples of students in grades 9 through 12. In 1989, the Centers for Disease Control (CDC) conducted the Secondary School Student Health Risk Survey[4] to measure the prevalence of HIV-related knowledge, beliefs, and behaviors among US high school students. In 1990, using a similar methodology, CDC's Youth Risk Behavior Survey expanded this effort by measuring priority health-risk behaviors for HIV infection and other major causes of morbidity and mortality.[9] Eight HIV-related questions were either identical on the two surveys or were similar enough to allow comparisons.

In this analysis we examine the prevalence of HIV-related sources of information, instruction, and knowledge and the prevalence of selected HIV-related sexual and drug use behaviors and assess changes in these rates from 1989 to 1990. We also examine relationships among the variables in 1990 to determine predictors of HIV-related sexual and drug use behavior and compare these findings with those from analyses of the 1989 data.[3,5] We hypothesized that greater levels of HIV knowledge would be negatively related to the risk behaviors and that the relationships would not change between the two time periods.

Methods

Study Design

By use of self-administered questionnaires, data were obtained from two independent samples of high school students who were surveyed in spring 1989 and spring 1990, respectively. Both were designed as probability samples of all 9th through 12th grade public and private school students in the United States, Puerto Rico, and the Virgin Islands. Schools were randomly selected within primary sampling units (counties or groups of counties), one or two classes per grade were randomly selected within schools, and all students within selected classes were eligible to participate. The sampling frames were stratified by geographic region and metropolitan status and additionally by race/ethnicity in the

1990 Youth Risk Behavior Survey. Both samples were selected with probability proportional to enrollment size. Schools with substantial numbers of Black and Hispanic students were oversampled to ensure adequate numbers of students in these two groups. Weighting factors were developed to compensate for unequal selection probabilities and to adjust for nonresponse in both surveys.

Additional information about the 1989 Secondary School Student Health Risk Survey sample can be found elsewhere.[3-5] Like the 1989 survey, the 1990 Youth Risk Behavior Survey questionnaire was designed for a seventh-grade reading level and administered in the classroom by professionally trained data collectors. Parents provided consent for students to participate, and student anonymity was protected.

Data Analysis

We used *t* tests to determine significant differences between 1989 and 1990 for selected student responses. Following previous studies of the 1989 Secondary School Student Health Risk Survey,[3,5] we examined the 1990 Youth Risk Behavior Survey data to determine relationships between two dependent variables (sexual behavior [having had two or more sex partners during a lifetime] and injecting drug use [having ever injected illicit drugs]) and two independent variables (having received HIV instruction [yes/no] and having correct knowledge about HIV [based on responses to two items]). (In establishing models for the 1990 survey data, we made every effort to replicate the two previous analyses of the 1989 survey data. However, in the 1989 analyses, 17 items—instead of 2—were available to measure HIV knowledge. Also the models for the 1989 survey included the interactions between HIV instruction and sex and between instruction and race/ethnicity. We excluded these interaction terms from our models for the 1990 survey because of the relatively high correlations between the terms and their main effects.) We used stepwise multiple logistic regression and controlled for age, sex, and race/ethnicity in each model.

All analyses were conducted on weighted data. We calculated confidence intervals (CIs) and statistical tests by using SESUDAAN procedures,[10] which account for the complex sample design. Results were considered significant if the *P* value for the calculated statistic was less than or equal to .05.

vided usable data. Comparisons of selected and participating schools by region, metropolitan status, and race/ethnicity (in the 1989 survey)[5] and by region and metropolitan status (in the 1990 survey) showed small differences within each category, suggesting minimal nonresponse bias among the samples.

Demographic characteristics of the samples for both years showed that participants were distributed almost evenly by grade and by sex. With two exceptions, the samples also had similar distributions by age group and by race/ethnicity. The 1989 and 1990 samples differed in the weighted proportion of Black students (9.1% vs 15.2%) and the weighted proportion of students younger than 15 years of age (8.4% vs 13.1%). To determine whether these differences would influence results of the *t*-test analysis, we conducted additional multivariate analyses that took into account the demographic characteristics of the samples (data not shown). Controlling for age, sex, and race/ethnicity, we regressed each HIV-related measure on time. All significant changes observed in the *t*-test analysis were confirmed by the multivariate analysis, indicating that the small differences in the samples did not influence the changes we found in reported instruction, knowledge, or behavior from 1989 to 1990. (In fact, differences from 1989 to 1990 that were not statistically significant in the *t*-test analysis were significant in the multivariate analysis. Thus, the findings reported here from the *t*-test analysis are statistically more conservative.) Furthermore, the weighted percentages of White, Black, and Hispanic students in both surveys were not unlike the racial and ethnic distribution of 9th through 12th grade students in the United States, suggesting that the samples were representative of the general population of students.[5]

Instruction, Knowledge, and Behavior

In both years, students were asked whether they had been taught about the acquired immunodeficiency syndrome (AIDS) and HIV infection in school. The percentage of students receiving HIV instruction significantly increased from 53.7% in 1989 to 74.0% in 1990; these increases were evident for almost every demographic subgroup (Table 1). Moreover, a significantly greater proportion of students in 1990 (68.4%; 95% CI = 65.0, 71.7) than in 1989 (49.0%; 95% CI = 46.5, 51.5) reported that they knew where to get good information about AIDS/HIV infection. However, students were no more likely to talk about AIDS/HIV infection with their parents or other adult family members in 1990 (52.8%; 95% CI = 50.9, 54.8) than they were in 1989 (54.4%; 95% CI = 51.9, 56.8). And although students in 1990 (61.1%; 95% CI = 56.5, 65.6) were significantly more likely than those in 1989 (45.1%; 95% CI = 42.3, 48.0) to know that insects do not transmit the virus, significantly fewer students in 1990 (54.9%; 95% CI = 52.1, 57.7) than in 1989 (64.0%; 95% CI = 61.3, 66.7) reported that they knew the virus could not be transmitted from donating blood.

Essentially no change was observed from 1989 (8.1%; 95% CI = 6.6, 9.6) to 1990 (8.3%; 95% CI = 6.9, 9.7) in the proportion of students who reported that they were younger than age 13 when they first had sexual intercourse. However, in 1990, proportionately fewer students in most subgroups reported that they had had sexual intercourse (Table 2). Notably, these decreases were significant among White students and female students.

Similarly, the proportion of all students who reported having had two or more sex partners during their lifetime was lower in 1990 (36.3%) than in 1989 (40.1%) (Table 3). Although this decline was evident by age group, racial/ethnic group, and sex, with one exception the differences were not statistically significant. Among White students, a significantly smaller proportion reported two or more lifetime sex partners in 1990 than in 1989. For reported sexual intercourse with four or more partners, however, the decrease in prevalence between 1989 and 1990 was significant for all students; within subgroups, the decline was significant for 15- and 16-year-olds, White students, and female students (Table 4).

In 1990, 1.5% (95% CI = 1.0, 1.9) of students reported having ever injected illicit drugs. We were unable, however, to directly compare this estimate with that for 1989. Although the wording of the relevant questions was similar in 1989 and 1990, different criteria were used to define injecting drug use in the 1990 survey.[11] Likewise, we were unable to compare condom use from 1989 to 1990; however, for this behavior, the wording of the relevant questions differed. In 1989, students were asked about the frequency of condom use whenever they had sexual intercourse. In 1990, students were asked whether they had used a condom at last sexual intercourse.

Results of the multivariate analysis of the 1990 Youth Risk Behavior Survey data revealed that having lower levels of HIV knowledge, being male, being Black, and being in an older age group were all significantly associated with having had two or more lifetime sex partners (Table 5). A previous study of the 1989 Secondary School Student Health Risk Survey found that these same variables were significantly associated with having had two or more lifetime sex partners.[3] Importantly, after we controlled for demographic characteristics, students with lower levels of HIV knowledge were more likely to report two or more lifetime sex partners.

*$P < .05$.

Our analysis of the 1990 survey data also found that having lower levels of HIV knowledge, being male, and not being Black compared with other race/ethnic groups were all associated with reported lifetime drug injection (Table 6). Again, these results were consistent with those reported for 1989.[5] Notably, controlling for demographic characteristics, we found that students in 1990 who reported lower levels of HIV knowledge also were more likely to report ever injecting drugs. Lastly, although HIV instruction did not directly affect these behavioral outcomes, when we controlled for age, sex, and race/ethnicity, HIV instruction was positively associated with HIV knowledge in analyses of the 1990 data (similar to our findings for the 1989 data[5]).

Discussion

Programs to educate students about HIV have been implemented in many of the nation's schools.[12] But whether such programs are associated with improvements in HIV knowledge and changes in HIV-related risk behaviors is unclear. Few studies have examined changes over time, and the results are inconsistent. For example, in a study of adolescent decision-making regarding contraceptive use, sexually active adolescents visiting health clinics in San Francisco were surveyed in 1984 and 1985 and again in 1985 and 1986.[6] Researchers found no substantial increases in condom use among the participants, and large percentages of respondents continued to report multiple sex partners.

Other studies, however, have found differences over time. To compare risk behavior, one study used data from two matched samples—one from the winter of 1986 and the other from the fall of 1987—of unmarried young adults attending a university in California.[7] Researchers found that students in the later survey not only showed greater worry and concern about all sexually transmitted diseases, including AIDS, but also demonstrated behavioral changes. For example, the proportion of young adults who reported using condoms increased from 46% in 1986 to 62% in 1987.

Respondents surveyed in 1987 also were significantly more likely than those surveyed in 1986 to report delaying sexual involvement, avoiding anal sex, and asking their partners about prior sexual behavior.

Differences also emerged from a Massachusetts study that used data from two independent phone surveys of 16- to 19-year-old adolescents who were selected by statewide random-digit dialing; this study was conducted in August through September of 1986 and 1988.[8] The proportion of teenagers who had a teacher who discussed AIDS in school increased from 52% in 1986 to 82% in 1988. Knowledge about how AIDS is transmitted also was more widespread in 1988. Between 1986 and 1988 some behavioral changes were found as well: reported intravenous drug use declined from 1% to 0.1%; the proportion of sexually active teenagers who reported having made changes in sexual behavior to avoid AIDS increased from 16% to 34%; and the proportion who reported using condoms in response to AIDS increased from 2% to 19%. However, the proportion of teenagers who reported having had sexual intercourse during the year preceding the survey increased from 55% to 61%.

In a retrospective assessment, 39% of inner-city adolescents surveyed in 1988 reported that concern about AIDS led them to make behavior changes during the 6 months preceding the survey.[13] Of those reporting behavior changes, 67% (25% of the total study group) reported that they used condoms, and 16% (6% of the total study group) reported that they were currently abstaining from sexual intercourse.

Although some important behavioral changes were noted in these studies (differences in methodology and samples may partially account for some of the inconsistencies in the results across studies), none represent a very broad cross-section of the adolescent population; therefore, all were unable to assess the impact of the nation's HIV education efforts on behavior. The 1989 Secondary School Student Health Risk Survey and the 1990 national school-based Youth Risk Behavior Survey are the first surveys to measure HIV-related instruction, knowledge, and behaviors among national probability samples of high school students in the United States. Together these surveys provide a unique opportunity to assess possible changes at the national level.

The significantly greater proportion of high school students who in 1990 reported receiving school-based HIV instruction may indicate that more schools are establishing such programs or are expanding current programs to reach students at multiple grade levels. The quality and content of these programs probably vary. Such variation may partly explain our finding that students in the 1990 survey were more knowledgeable about one aspect of HIV transmission but less knowledgeable about another.

Coupled with the increase in school-based HIV instruction, the decreases we found in certain HIV-related behaviors also are encouraging, even though the decreases were not significant for all subgroups of students. These observations are particularly important given the previous trend of increasing sexual activity among selected subgroups of US adolescents over almost two decades.[14,15]

School-based HIV instruction (which appears to be reaching more students over time) and its impact on HIV knowledge may have contributed to some of the positive behavioral changes we observed. Although the survey data do not allow us to make inferences about cause and effect, the similar associations for both surveys suggest that HIV knowledge—which, in turn, was found to be positively associated with HIV education both in the current analysis and in previous analyses[5]—may be one important determinant of HIV-related risk behavior among US high school students. Furthermore, despite the limitations of our knowledge measure in the 1990 survey, the findings from our multivariate analyses held across surveys.

It is important to note that although these findings are suggestive, the relationship between HIV education or knowledge and risk behavior is still unclear. A recent study found an association between AIDS education and (1) increases in the consistency of condom use and (2) decreases in the frequency of intercourse and in the number of sexual partners among teenage men in the United States.[16] AIDS knowledge also was found to be positively correlated with behavior change in an earlier study of inner-city high school students.[13] Other studies of adolescents or young adults, however, have failed to show an association between AIDS-related knowledge and behavioral change or intentions.[8,17-19] Additional research (notably, intervention studies currently under way) may help identify the mechanisms by which education or knowledge can influence behavior in relation to HIV.

It is also important to recognize some limitations of our data. Because behaviors may differ between in-school and out-of-school adolescents, our results can be generalized only to the adolescent population in school. This limitation becomes more pronounced among older youth, because dropout rates increase with student age.

The limitations of self-reported data also apply to our findings; despite extensive measures to ensure student privacy and anonymity, underreporting or overreporting may have occurred. Underreporting by females or overreporting by males may partially explain our finding that males report greater levels of sexual activity than females. Such potential bias, however, is likely to operate in a similar fashion across surveys and therefore is unlikely to influence the changes we observed from 1989 to 1990.

Finally, we must be cautious about interpreting change with only two points in time. Clearly, more data will be needed to identify trends. We can be encouraged, however, by the consistent pattern of decline that emerged for many of these reported risk behaviors—declines that were significant over the 1-year period for some groups of students.

The results of national school-based surveys are useful for assessing our efforts to educate youth about HIV infection. Although limited to two points in time, the behavioral changes we observed between 1989 and 1990 provide information about directions we need to encourage and about those where we need to redouble our efforts. Our findings suggest that school-based HIV instruction may be an important part of the national effort to help us improve the health and well-being of our youth. □

Tobacco Use by Black and White Adolescents: The Validity of Self-Reports

Karl E. Bauman, PhD, and Susan E. Ennett, PhD

ABSTRACT

Objectives. **Previous studies concluded that Black adolescents use tobacco and other drugs less than White adolescents. The Black–White differences typically were attributed to variations in background and life-style. The objective of the research reported in this paper was to determine whether the presumed difference in tobacco use is due to Black–White differences in the validity of self-reports.**

Methods. **We used biochemical measures to compare the validity of self-reports of tobacco use by 1823 Black and White adolescents and to assess the contribution of variation in validity to Black–White differences in reported tobacco use.**

Results. **The sensitivity of Blacks' reports was significantly less than the sensitivity of Whites' reports. The specificity of Whites' reports was significantly less than the specificity of Blacks' reports. Much of the Black–White differences in reports of cigarette smoking and tobacco use were due to Black–White differences in validity.**

Conclusions. **Studies of Black–White differences should adjust for the invalidity of reports or acknowledge that much of the difference may be due to measurement error. (*Am J Public Health.* 1994;84:394–398)**

Introduction

Studies consistently show that Black adolescents are less likely than White adolescents to use drugs.[1-10] This difference typically is attributed to differences in background and life-style. For example, differential vulnerability to models of drug behavior[8] and the substantial impact on youth of Black churches' fundamentalist orientation[9] have been offered as explanations for relatively low drug use by Black adolescents.

All prior studies of Black–White differences in adolescent drug use have relied entirely on self-reports of drug use. Therefore a very different type of explanation for the difference is that Blacks underreport their drug use more than Whites and Whites overreport their drug use more than Blacks. Although this possibility is sometimes acknowledged, it is more often ignored or dismissed as unlikely.[1,9] Only one study has empirically addressed the possibility that Black adolescents might underreport their drug use more than White adolescents. Mensch and Kandel[11] found that among youths who had reported in 1980 that they had used drugs, more Blacks than Whites reported in 1984 that they had never used drugs. The one study of young adults that compared Blacks and Whites concluded that Blacks underreported smoking more than Whites.[12]

In this paper we compare the validity of self-reports of tobacco use by Black and White adolescents and examine the contribution of invalidity to the Black–White difference in self-reported use. We use biochemical indicators as the standards for self-reports, with full recognition that researchers sometimes use self-reports as the standards for biochemical measures and that the biochemical measures we used are not perfect indicators of tobacco use.[13,14]

Methods

The data were gathered for baseline measures to study the influence of mass media campaigns to prevent smoking. Probability samples of households were identified in 10 standard metropolitan statistical areas of the southeastern United States and screened for adolescents aged 12 through 14 years. From April 1, 1985, through October 13, 1985, interviewers attempted to gather data from all eligible adolescents in these households. When more than one adolescent aged 12 through 14 years resided in a household, one was randomly selected to serve as a subject. Of the 2534 adolescent subjects estimated to be eligible for study, 2102 (83%) participated by completing questionnaires in their homes. Subjects averaged 1 hour to complete the self-administered questionnaire and provide biochemical specimens to measure cigarette smoking and tobacco use. Subjects who were not Black or White and subjects who had missing information on any variable were eliminated from these analyses. More detail on the study methodology is available elsewhere.[15]

Race was determined by interviewer observation when possible and by interview when necessary. The use of observation as the primary procedure to classify Blacks and Whites was intended to reduce measurement error by minimizing reading and recording errors and by eliminating missing information. In nearly all cases, Whites and Blacks could be readily distinguished by interviewer observation. When the distinction between Blacks and Whites was not obvious the interviewer asked the subject to indicate his or her race, using standard categories. Asking subjects to indicate their race from a range of choices is a widely used research procedure because race determination sometimes is not straightforward. Interviewers received 3 days' training and were closely supervised throughout data collection. We received no reports during our many discussions with interviewers that this procedure produced error.

The percentages of girls among Whites (47.9%) and Blacks (50.6%) were not significantly different ($\chi^2 = 1.1$, $P = .296$, n = 1823). Similarly, the average ages of Whites (mean = 13.1 years) and Blacks (mean = 13.0) were not significantly different ($t = 1.0$, $P = .348$, n = 1823). Parent education was a six-category variable ranging from less than high school graduate to more than 4 years of college education. The education of White and Black parents differed ($\chi^2 = 72.7$, $P = .0001$, n = 1564); White parents were more likely than Black parents to have graduated from high school (81.7% vs 62.8%) and from college (19.0% vs 10.1%).

The primary self-report measure of cigarette smoking was a single questionnaire item that was agreed on for use by investigators funded by the National Cancer Institute[16] and validated by earlier research.[17] The question was "Which statement below BEST describes YOUR current cigarette smoking behavior?" The 13 response categories ranged from "I have never smoked" to "I smoke two packs or more each day." Subjects who said they usually smoked one or more cigarettes per week were considered to be smokers. Supplementary analyses used a question to measure recent smoking ("How long has it been since you last even puffed on a cigarette?"), with eight response categories ranging from "less than 3 hours ago" to "more than 15 hours ago." Smoking within the previous 9 hours was considered recent smoking. The 12 Black subjects and 18 White subjects who reported that they had used marijuana, cigars, or pipes within the previous 9 hours were excluded to preclude their influence on the alveolar carbon monoxide measure described below. Subjects were also asked, "When did you last use chewing tobacco or snuff?" The nine response categories ranged from "never used" to "7 or more days ago." Smokers and any subjects who reported that they had used chewing tobacco or snuff within the previous 3 days were considered to be tobacco users.

Carbon monoxide is a major measurable chemical in tobacco smoke. Each subject provided an alveolar breath sample by taking a deep breath, holding the breath for 20 seconds, blowing half of the breath into the open air, and blowing the remainder of the breath into a bag. The breath was analyzed for level of carbon monoxide, and subjects with levels of 9 ppm or higher were considered to be smokers.[18]

Cotinine is used to indicate nicotine exposure. Each subject deposited 1.5 mL of saliva into a vial. The saliva was frozen on the day of collection, stored until analysis, and analyzed for cotinine by radioimmunoassay. Subjects with cotinine levels of 10 ng/mL or higher were considered to be users of tobacco.[18]

All subjects were told before completing the questionnaires that the biochemical measures would be used to check their reports of cigarette smoking. Earlier studies suggest that such a disclosure enhances the validity of self-reports.[19,20]

Carbon monoxide is used as the standard for self-report of cigarette smoking and cotinine is used as the standard for self-report of tobacco use. Sensitivity is the number of self-reported users per 100 users according to the standard. Specificity is the number of self-reported nonusers per 100 nonusers according to the standard. Underreports and overreports are said to occur when biochemical and self-report measures are incongruent; underreports are self-reports of nonuse when the biochemical measure is positive and overreports are self-reports of use when the biochemical measure is negative. Considerations that must accompany these definitions are addressed in the first part of the discussion section of this paper.

TABLE 1—Self-Reported Cigarette and Tobacco Use by Black and White Adolescents

	% Reporting Use				
	Black (n = 530)	White (n = 1293)	χ^2	*C*	*P*
Cigarettes	.4	4.6	20.8	.11	<.0001
Tobacco	1.7	9.9	36.4	.14	<.0001

Note. *C* = contingency coefficient.

Results

As other studies have shown, Whites are more likely than Blacks to report that they smoke cigarettes and use tobacco (Table 1).

Table 2 shows the sensitivities and specificities for self-reports of cigarette smoking and tobacco use. Blacks were more likely than Whites to underreport use of these substances. Whites were more likely than Blacks to overreport use. The Black–White difference in sensitivity is much larger than the Black–White difference in specificity. Because the vast majority of subjects are not users, however, the small Black–White difference in specificity can contribute to the Black–White difference in self-reported use. The greater use reported by Whites than by Blacks appears to be influenced both by Black underreports and by White overreports.

Do Black–White differences in validity of reports contribute much to the Black–White differences in smoking and tobacco use? To address this question directly, we compared the ratios of White-to-Black use from self-report and biochemical measures. For this comparison we assumed that most if not all of the difference in ratios is attributable to the invalidity of self-reports. Table 3 shows the percentages of cigarette and tobacco users according to self-report and biochemical measures for Blacks and

Carbon monoxide	4.3	1.3	3.3
Tobacco			
Self-report	9.9	1.7	5.8
Continine	11.4	3.0	3.8

Whites. The ratios of the White to Black percentages are shown in the right column. Of particular interest is that the ratios of White to Black use are substantially smaller for biochemical measures than for self-reports, suggesting that Black–White differences in cigarette and tobacco use are substantially increased by Black–White differences in invalid self-reports.

Another way to describe the contribution of invalidity to the difference in Black and White-self-reports is to first adjust the self-reports of Blacks for the sensitivity and specificity of Whites and then compare the White-to-Black ratio of unadjusted rates to the ratio of White unadjusted to Black adjusted rates. The extent to which the first ratio is larger than the second reflects the contribution of invalidity to Black–White differences in self-reports. Parallel comparisons can be made with White self-reports adjusted for Black sensitivity and specificity.

The procedures for calculating the adjusted rates are as follows. Sensitivity and specificity, expressed as percentages in Table 2, are converted to proportions by dividing by 100. To derive the number of Blacks who smoke under the conditions of White sensitivity and specificity, we summed two products: (1) White sensitivity times the number of Blacks with carbon monoxide levels of 9 ppm or higher ($.625 \times 7 = 4.375$) and (2) 1.00 minus white specificity ($1.00 - 0.98 = 0.02$) times the number of Blacks with carbon monoxide levels of less than 9 ppm ($0.02 \times 523 = 10.460$). The adjusted percentage of self-reported Black smokers is the above sum ($4.375 + 10.460 = 14.835$) per 100 Black subjects ($14.835/530 \times 100 = 2.8$). The same procedure was used to derive a rate of 5.6% of Black self-reported tobacco users adjusted for the sensitivity and specificity of Whites. We used the same procedure to derive rates for Whites that were adjusted for Black sensitivity and specificity. The percentages of White self-reported cigarette and tobacco users, adjusted for Black sensitivity and specificity, are 0.4 and 2.7, respectively.

The unadjusted White-to-Black ratio of 11.5 for cigarette use (Table 3) is much larger than the 1.6 ratio of White unadjusted to Black adjusted rates (4.6:2.8) and the 1.0 ratio of White adjusted to Black unadjusted rates (0.4:0.4). For tobacco use, the unadjusted White-to-Black ratio of 5.8 is substantially larger than the 1.8 ratio of White unadjusted to Black adjusted rates (9.9:5.6) and the 1.6 ratio of White adjusted to Black unadjusted rates (2.7:1.7). These comparisons, like those presented earlier that compared the ratios of White to Black use from self-report and biochemical measures (Table 3), suggest that a substantial portion of the Black–White difference in self-reported use is due to Black–White differences in the validity of self-reports.

The findings presented above use smoking within a week to identify self-reported smokers. Because carbon monoxide can be detected for about 9 hours, reports of smoking within the previous 9 hours might be more meaningful for determining sensitivity and specificity. However, sensitivity and specificity are changed only slightly when recency is substituted for smoking. Specifically, for Blacks, sensitivity for smoking and tobacco use were identical when the different self-reports of cigarette smoking were used, and specificity was 2.5% lower with the recency measure. When recency was substituted for smoking within a week for Whites, sensitivity of smoking decreased from 62.5% to 53.6% and sensitivity of tobacco use decreased from 55.8% to 50.3%; specificity decreased by 0.2% and 1.5% for smoking and tobacco use, respectively.

Discussion

In this paper we treat biochemical indicators as standards for self-reports of smoking and tobacco use. There are, however, no gold standards for these behaviors. Recent comprehensive reviews of the power, limitations, and range of interpretation of biochemical measures of smoking are available elsewhere.[13,14] Neither of the biochemical indicators has a point at which self-reported behaviors can be determined precisely. The amount of time carbon monoxide and cotinine remain detectable in body fluids varies somewhat by various characteristics,[18] and carbon monoxide level can be influenced by factors such as ambient tobacco smoke and automobile exhaust. We set our

cut-point for carbon monoxide where contribution from sources other than active smoking is unlikely, and the cut-points for both biochemical measures are those commonly used by other researchers. Different self-report measures of cigarette smoking produced sensitivity virtually identical to the values in our tables. Extensive research has failed to find substances other than tobacco that produce cotinine levels as high as those we used to indicate tobacco use, but such substances may be discovered in the future.

It is possible that Blacks and Whites have such large differences in carbon monoxide and cotinine levels for reasons other than smoking and tobacco use that those reasons, rather than the invalidity of self-reports, explain the Black–White difference in biochemical and self-report congruency. If this is the case, then what we consider to be Black–White differences in the validity of self-reports in our data are not differences in invalidity at all. Metabolism of nicotine or excretion of cotinine may vary by race in young adults and therefore in young adolescents, and may thereby influence estimates of sensitivity and specificity.[21] We assume that such factors are too weak to entirely explain the large Black–White differences in sensitivity in our data and the stability of estimates across self-report and biochemical measures. Until future research clarifies this point, however, it must be recognized that what appear to be large Black–White differences in the validity of self-reports may actually reflect something else.

We would have preferred to have more Black smokers and tobacco users available for estimating the sensitivity of self-reports. Indeed, of the 530 Black subjects, only 2 reported smoking and 7 reported tobacco use. Even with the small numerators, however, the differences between Blacks and Whites were statistically significant.

Invalidity may contribute even more to the difference between Black and White self-reports in studies that do not inform subjects that their self-reports will be compared with biochemical indicators. It is likely that in our study validity was increased, and perhaps the difference in invalidity between Blacks and Whites was reduced, because our subjects were told that their answers would be checked by the biochemical indicators.[19,20]

An advantage of the data used in this study is that they did not depend on school enrollment. Most studies of adolescent drug use are based on data collected in schools. The higher school dropout rate of Blacks and the high use of drugs reported by dropouts[22] and students with high absenteeism[23] complicate Black–White comparisons when school-based data are used.

Others have argued that self-reports obtained from adolescents in their homes are less valid than those gathered in schools.[23] The extent to which this is true could limit the generalizability of our findings because our data were collected in homes and many studies of adolescents use data collected in schools. However, the only examination of this possibility that used a true experimental design and thereby avoided many of the potential confounds, such as markedly different sample frames and instrumentation, found no difference in drug use between data gathered in homes and in schools.[24]

Our findings may not be generalizable to drugs other than tobacco. Drug behaviors are significantly correlated, however, and there are compelling reasons for subjects to underreport their use of other drugs in addition to tobacco. Our findings indicate that Black–White differences in invalidity should not be readily dismissed when Black–White comparisons are made.

Others have identified variables that need to be taken into account when attempting to explain Black–White differences in adolescent tobacco use. They include religion, vulnerability, parents' and friends' use, availability, and risk taking.[5,8,9] Our findings suggest that differential invalidity is one of the more important explanatory variables.

Conclusions

Future studies of Black–White differences in drug use that rely on self-reports should account for invalid measurement before proceeding to examine variables of more theoretical and practical interest, or they should give more credence to the possibility that the differences they attempt to explain may be due in large part to differential validity. □

Smokeless Tobacco Use and Increased Cardiovascular Mortality among Swedish Construction Workers

Gunilla Bolinder, MD, Lars Alfredsson, PhD, Anders Englund, MD, and Ulf de Faire, MD, PhD

ABSTRACT

Objectives. Little is known about the risks of cardiovascular disease associated with the use of smokeless tobacco, which produces blood nicotine levels similar to those caused by cigarette smoking.

Methods. Male Swedish construction industry employees (n = 135 036) who attended a health examination were followed by studying cause-specific mortality during a 12-year period. The study population comprised 6297 smokeless tobacco users, 14 983 smokers of fewer than 15 cigarettes per day, 13 518 smokers of 15 or more cigarettes per day, 17 437 ex-smokers, 50 255 "other" tobacco users, and 32 546 nonusers.

Results. The age-adjusted relative risk of dying from cardiovascular disease was 1.4 for smokeless tobacco users and 1.9 for smokers of 15 or more cigarettes per day, compared with nonusers. Among men aged 35 through 54 years at the start of follow-up, the relative risk was 2.1 for smokeless tobacco users and 3.2 for smokers. When data were adjusted for body mass index, blood pressure, and history of heart symptoms, the results were essentially unchanged. Cancer mortality was not raised in smokeless tobacco users.

Conclusions. Both smokeless tobacco users and smokers face a higher risk of dying from cardiovascular disease than nonusers. Although the risk is lower for smokeless tobacco users than for smokers, the excess risk gives cause for preventive actions. (*Am J Public Health.* 1994;84:399–404)

Introduction

Although there is well-established evidence for a causal link between cigarette smoking and cardiovascular damage and disease,[1] the reasons behind the development of atherosclerosis in smokers are not fully understood. The nicotine content of cigarette smoke is a suspected contributor to vascular damage, as nicotine has a variety of potentially relevant cardiovascular effects. Nicotine most likely promotes atherosclerotic disease by its actions on lipid metabolism and coagulation,[2–5] by hemodynamic effects,[1,4] and/or by causing endothelial injury.[6]

However, there have been no studies on long-term exposure to pure nicotine in humans, and only limited experience from animal studies.[7] Therefore, users of smokeless tobacco (snuff) present an excellent opportunity for studying the effects of exposure to nicotine without simultaneous exposure to carbon monoxide and other combustion products of tobacco smoke. It has been shown that the use of smokeless tobacco, during which nicotine is absorbed through the buccal mucosa, produces maximum blood levels of nicotine similar to those produced by cigarette smoking and results in a larger overall exposure to nicotine owing to prolonged absorption.[8,9]

In a recent cross-sectional study, it was observed that middle-aged and older smokeless tobacco users had a significantly higher prevalence of hypertension than either nonusers or smokers.[10] The smokeless tobacco users were also affected more than nonusers by cardiovascular symptoms. During a 4-year follow-up period, smokeless tobacco users had a higher risk than nonusers of disability retirement due to cardiovascular diseases. The excess risk was quite similar to the excess risk observed in smokers.

The aim of the present study was to investigate whether long-term exposure to smokeless tobacco is associated with an excess risk of dying from cardiovascular disease in users compared with nonusers and to compare this potential excess risk among smokeless tobacco users with the corresponding excess risk among cigarette smokers.

Materials and Methods

Subjects

The study population comprised 135 036 men who had received medical checkups under the auspices of the Swedish Construction Industry's Organization for Working Environment Safety and Health during the years 1971 through 1974. The cohort included construction workers, electricians, painters, sheet metal workers, and other construction industry employees in the whole of Sweden. The invitation to the voluntary medical examination was sent out by the construction site staff and about 75%

55–65 y	5 642	1734	2 132	1 383	4 846	15 737
All	32 546	6297	14 983	13 518	17 437	84 781

Note. Those who had mixed tobacco use or who smoked pipes or cigars (50 255 subjects, or 37.2% of the total sample of 135 036) are excluded from table.

responded to it. In 1974 there were 183 865 registered workers in the Swedish construction industry; it is not known to what extent the nonattending workers (≈25%) were not reached by the invitation or were not willing to come. Women (< 0.5% of workers in the construction industry) were excluded from the study.

Procedures

A standardized program was followed for the medical examination. Body weight and height were determined. Blood pressure was measured after 5 minutes of rest in a supine position. A standard mercury manometer on the upper arm was used to record the systolic level when phase 1 (Korotkoff) sounds were heard and the diastolic level at phase 5 (disappearance of sounds). Blood pressure was recorded to the nearest 2 mm Hg. Heart rate was recorded as beats per minute, simultaneously with the blood pressure measurement.

Tobacco habits by kind of tobacco use (cigarettes, smokeless tobacco, pipe, cigar, or mixed use), amount of smoked tobacco, and duration of the tobacco consumption habit were recorded with the aid of a questionnaire that the subject filled out together with a nurse. The questionnaire also requested information about present or past history of symptoms and diseases as well as current medication.

The members of the study population identified between 1971 and 1974 and who were alive on January 1, 1974, were followed regarding cause-specific mortality during the period 1974 through 1985 with the aid of the National Cause of Death Register,[11] with certification of the underlying cause of death according to the *International Classification of Diseases*, 8th revision (ICD-8). The underlying cause of death is defined as the illness that started the chain of events that directly led to death. The diagnoses specifically studied were ischemic heart disease (ICD 410–414), cerebrovascular disorders (ICD 430–438), all cardiovascular diagnoses (ICD 390–458), and all malignant neoplasms (ICD 140–209).

Analyses

The classification of tobacco habits was aimed at isolating subjects in groups with a single type of exposure to tobacco. Tobacco users were divided into smokeless tobacco users, smokers, ex-smokers, and others. Nonusers were subjects who reported that they had never used tobacco. Smokers were divided into cigarette smokers who smoked fewer than 15 cigarettes per day and those who smoked 15 cigarettes per day or more, both groups being without any other kind of former or present tobacco use. Smokeless tobacco users were subjects who reported only present smokeless tobacco use and no former or present smoking. Ex-smokers were cigarette smokers who had never smoked a pipe, smoked cigars, or used smokeless tobacco and who had quit smoking; they were further divided into those who had not smoked for less than 5 years and those who had not smoked for 5 or more years. "Others" were all subjects with mixed tobacco use or subjects who smoked a pipe or cigars. The duration of the tobacco habit was divided into less than 15 years and 15 or more years. Because smokers of more than 15 cigarettes per day consume about the same amount of nicotine as daily smokeless tobacco users,[9,12] special emphasis should be placed on this group when interpreting the analysis.

In the analysis, blood pressure was divided into four categories: systolic blood pressure ≤ 140, 141–159, 160–179, and ≥180 mm Hg and diastolic blood pressure <85, 85–94, 95–104, and ≥105 mm Hg. Blood pressure and heart rate data were missing for 0.2% of the subjects. The body mass index was calculated as body weight in kilograms divided by height in meters squared. Body mass indexes were divided into four categories: ≤20.0, 20.1–25.0, 25.1–30.0, and >30.0.

Relative risks of death due to specific causes, together with 95% confidence intervals, were estimated for subjects with different tobacco habits in comparison with the nonusers. To adjust for potential confounding factors, the Mantel-Haenszel procedure was used[13] and 95% confidence intervals were estimated according to Greenland et al.[14] Potential confounding factors were considered to be age (5-year brackets), area of domicile, blood pressure, blood pressure medication, previous cardiac symptoms, diabetes, and body mass index.

Analyses of the relationship between different tobacco habits and mortality were performed for the entire cohort, for workers entering the study at ages 35 through 54 years, and for those entering the study at ages 55 through 65 years.

Results

The distribution of the study population by tobacco habit is shown in Table 1; 24.1% of the subjects were nonusers, 4.7% were smokeless tobacco users, 11.1% were smokers of fewer than 15 cigarettes per day, 10.0% were smokers of more than 15 cigarettes per day, and 12.9% were ex-smokers. The 37.2% of the population who smoked pipes or cigars or who had mixed tobacco use (n = 50 255) were excluded from all analyses.

During the follow-up period (1974 through 1985), there were a total of 8293 deaths in the whole study cohort. Fifty-seven percent of the deaths occurred in the analyzed tobacco-use groups: nonusers, 1322; smokeless tobacco users, 440; smokers of fewer than 15 cigarettes per day, 900; smokers of 15 or more cigarettes per day, 923; and ex-smokers, 1126. Cardiovascular disease was the most common cause of death among the construction workers. Ischemic heart disease caused 38% of the deaths in the whole study population, implying a crude cumulative mortality of 2.3% during the 12-year follow-up period.

TABLE 2—Observed Numbers of Deaths and Relative Risks (RRs)[a] for Causes of Death for Different Tobacco Habit Groups Compared with Nonusers

Cause of Death	Nonusers[b] (At-Risk n = 32 546)	Smokeless Tobacco Users (At-Risk n = 6297)		Smokers, <15 cig/d (At-Risk n = 14 983)		Smokers ≥15 cig/d (At-Risk n = 13 518)		Ex-Smokers, 1–5 y (At-Risk n = 6761)		Ex-Smokers, >5 y (At-Risk n = 9800)	
	No.	No.	RR (95% CI)	No.	RR (95% CI)	No.	RR (95% CI)	No.	RR (95% CI)	No.	RR (95% CI)
All cardiovascular disease	641	220	1.4 (1.2, 1.6)	450	1.8 (1.6, 2.0)	381	1.9 (1.7, 2.2)	169	1.4 (1.1, 1.6)	402	1.1 (0.9, 1.2)
All cancer	372	96	1.1 (0.9, 1.4)	216	1.5 (1.3, 1.8)	276	2.5 (2.2, 3.0)	119	1.6 (1.3, 2.0)	249	1.3 (1.1, 1.6)
All causes	1322	440	1.4 (1.3, 1.8)	900	1.7 (1.6, 1.9)	923	2.2 (2.0, 2.4)	350	1.3 (1.2, 1.5)	776	1.1 (1.0, 1.2)

Note. The deaths of 3582 men who were pipe or cigar smokers or had a mixed tobacco use habit are not presented in the table. For 876 ex-smokers (5%), length of time since quitting smoking was unknown; these ex-smokers were not included in this analysis. CI = confidence interval.
[a]Adjusted for age in 5-year intervals and for region of origin.
[b]Nonusers are the referent category (RR = 1.0).

Table 2 shows the age-adjusted relative risks of dying of cardiovascular disease, malignant tumors, and any cause for different tobacco-use groups compared with the nonusers. The excess risk of dying of cardiovascular disease was most pronounced for smokers, with a dose–response relation. In ex-smokers, the excess risk diminished with the time since smoking was stopped. Smokeless tobacco use was also found to be associated with an excess risk of dying of cardiovascular disease, whereas regarding death from cancer, no excess risk was observed. Although the present study did not analyze different cancer diagnoses in detail, it was obvious that smoking had a dose–response relationship to overall cancer risk and that the excess risk diminished gradually with the time since smoking was stopped.

Table 3 shows the results of the analysis of more specific causes of death in workers in two age groups. Higher relative risks were observed in the younger than in the older group for both smokeless tobacco users and smokers, compared with the nonusers. For smokeless tobacco users compared with nonusers, the relative risk of dying of cardiovascular disease was 2.1 (95% confidence interval [CI] = 1.5, 2.9) for those in the younger group and only 1.1 (95% CI = 1.0, 1.4) for those in the older group.

Death from stroke was less common than death from ischemic heart disease, but with regard to tobacco habits, the risk patterns for ischemic heart disease and stroke were the same. The relative risk of stroke among the younger smokeless tobacco users was close to 2, compared with the nonusers, but the number of cases was small and therefore the confidence interval was wide.

Lung cancer was studied specifically to evaluate whether hidden smokers could be found among the declared smokeless tobacco users. Three deaths from lung cancer were found in this group, whose relative risk compared with the nonusers was 0.9 (95% CI = 0.2, 3.0).

When potential confounding due to age, area of domicile, body mass index, blood pressure, diabetes, and history of heart symptoms or blood pressure medication at the time of entering the study was analyzed according to the Mantel-Haenszel procedure, the relative risks of death from cardiovascular diseases remained essentially unchanged. For cancer and overall mortality, no changes in the relative risk estimates were found when confounding factors were considered.

It was not considered meaningful to evaluate the duration of the tobacco habit in relation to cardiovascular mortality because very few subjects in age groups prone to various cardiovascular manifestations (i.e., those older than 45 years) exhibited a duration of tobacco use of less than 15 years, as most tobacco users start the habit at a young age. Eighty-seven percent of the cardiovascular deaths among smokeless tobacco users were associated with a tobacco habit duration of more than 15 years at the time the subjects entered the study. The corresponding figure for smokers of fewer than 15 cigarettes per day was 89%; for smokers of 15 or more cigarettes per day, the figure was 97%.

Figure 1 shows, for subjects who entered the study at ages 35 through 54 years, the relative risk of dying of ischemic heart disease for subjects in different tobacco-use categories compared with the nonusers. For smokeless tobacco users, the risk of death from ischemic heart disease was higher than that of nonusers and ex-smokers but lower than that of cigarette smokers.

Discussion

The present study of cardiovascular and cerebrovascular mortality in a cohort comprising more than 6000 smokeless tobacco users is the first observational epidemiological cohort study with the possibility of comparing a large group of smokeless tobacco users with both smokers and subjects not using any kind of tobacco. The results indicate an apparent excess risk of death from cardiovascular and cerebrovascular diseases of about 40% to 100% among smokeless tobacco users, compared with nonusers, when possible confounding factors are taken into account. Smokers face even higher risks of both cardiovascular and cerebrovascular causes of death.

In a recent case–control study from northern Sweden encompassing 35- through 64-year-old men with a first myocardial infarction and population-derived controls, smoking but not the use of smokeless tobacco was associated with an increased risk of myocardial infarction.[15] These results, which are contradictory to ours, could be due to differences in study design and composition of reference groups. Reasonably, the power to detect potential hazard effects from smokeless tobacco use is greater in an observational cohort study

TABLE 3—Cause-Specific Mortality among Swedish Construction Workers during 12-Year Follow-Up after 1971–1974 Health Examination

Cause of Death	Nonusers[a]	Smokeless Tobacco Users		Smokers, <15 cig/d		Smokers ≥15 cig/d		Ex-Smokers, 1–5 y		Ex-Smokers, >5 y

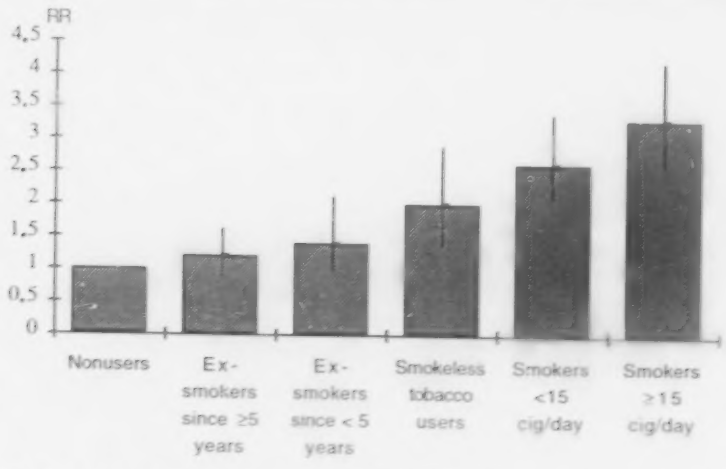
Note. For some ex-smokers (335 [4.1%] of those aged 35–54 years at entry and 110 [2.3%] of those aged 55–65 years at entry), length of time since quitting smoking was unknown; these ex-smokers were not included in this analysis. No. = number of deaths in the group; RR = relative risk, adjusted for age (5-year intervals) and for region of origin, for tobacco users compared with nonusers; CI = confidence interval.
[a]Nonusers are the referent category (RR = 1.0).



Note. Only subjects who were 35–54 years of age at entry into the study are included.

FIGURE 1—Adjusted relative risk (RR), together with 95% confidence interval, of dying due to ischemic heart disease among subjects in different tobacco habit groups as compared with nonusers.

with 3159 deaths due to ischemic heart disease (of which 172 were smokeless tobacco users) than in a smaller case-control study with 585 incident cases of myocardial infarction (of which 59 were smokeless tobacco users). In addition, our nonusers had never used any tobacco, whereas the nonusers in the case-control study included both former smokers and former smokeless tobacco users. The use of such "nonusers" might have contributed to a dilution of a possible excess risk for myocardial infarction in smokeless tobacco users.

Possible bias due to misclassification of both exposure and disease should be considered in our study. Assuming that smokers have a higher risk of dying from cardiovascular disease than smokeless tobacco users, a misclassification of smokers in the smokeless tobacco users group would lead to an overestimation of the relative risk associated with smokeless tobacco (i.e., the observed relative risk would be too high). How-

ever, if the proportion of misclassified smokers in the group classified as using smokeless tobacco was considerable, an elevated risk of dying from lung cancer would have been expected. Only three deaths from lung cancer were found among those classified as smokeless tobacco users. The corresponding relative risk of dying from lung cancer, compared with nonusers, was 0.9 (95% CI = 0.2, 3.0). In addition, different kinds of smokers or smokeless tobacco users wrongly classified as nonusers would result in an underestimation of the correlation between smokeless tobacco use and mortality due to cardiovascular disease. On combining different sources of bias due to misclassification of exposure, one finds that an underestimation of the relative risk of death from cardiovascular disease associated with smokeless tobacco use is more likely than an overestimation.

No follow-up recording of subjects' tobacco habits after entry into the study has been made. The most common change in tobacco habits in adults is to quit using tobacco. If our subjects had quit using tobacco, the relative risk estimates might have been diluted compared with what would be expected if no change took place during the follow-up period. If smokeless tobacco users had a tendency to start smoking, the estimated relative risks for smokeless tobacco users would be exaggerated. Nearly all smokeless tobacco users had used smokeless tobacco for more than 15 years without smoking, so it is reasonable to assume that the possible influence of such changes has been small.

The completeness of the Swedish National Cause of Death Register is almost 100%, as all deaths are required to be registered.[16] The validity of the underlying causes of death stated in death certificates has been evaluated and found to be high regarding cardiovascular diseases, stroke, and cancer.[17] Possible misclassifications are not likely to be dependent on the type of tobacco habit and therefore should not affect the relative risk estimates.[18]

The relationship between smokeless tobacco use and mortality due to specific causes was scrutinized regarding potential confounding from age, area of domicile, body mass index, blood pressure, diabetes, and history of heart symptoms or blood pressure medication at the time of entering the study. Cardiovascular risk markers such as total cholesterol were not routinely measured at the time of the medical examinations of this cohort, and therefore it was not possible to adjust for hypercholesterolemia as a confounding factor in the analysis. Cholesterol and high-density lipoprotein cholesterol did not differ between smokeless tobacco users and nonusers in two studies of relatively young users of smokeless tobacco,[19,20] but significantly higher levels of plasma cholesterol were found in smokeless tobacco users in one study in which older users were also examined.[21] The body mass index of smokeless tobacco users is generally higher than that of nonusers and considerably higher than that of smokers,[10] possibly implying differences in lipoprotein levels. However, the body mass index regarded as a confounder in the analysis did not change the relative risk estimates for the association between smokeless tobacco use and mortality due to cardiovascular disease.

It was not possible to consider potential confounding due to alcohol use, as no information on alcohol use was included in the medical examination data for this cohort. There is a positive correlation between hypertension and alcohol consumption.[22] Other studies have shown that smokeless tobacco users consume more alcohol than nonusers.[19,20] Similarly, tobacco users tend to exhibit other risk behaviors more often than nonusers.[22] Considering the relative homogeneity of the study population—all of whom were construction industry employees—and the relative risk associated with smokeless tobacco use among subjects aged 35 through 54 years at entry into the study, as well as the relative risk associated with heavy alcohol consumption,[23] it is unlikely that differences in alcohol consumption (between smokeless tobacco users and nonusers) would explain the findings entirely. Moreover, the studies on the relationship between alcohol consumption and cardiovascular disease have been ambiguous.[24] There have been, however, no observations indicating a difference in alcohol consumption between smokeless tobacco users and cigarette smokers, and therefore the possible confounding effect of alcohol use can be suspected to be comparable for both kinds of tobacco use.

In a cross-sectional study of the health status of this cohort, systolic and diastolic blood pressure values were found to be significantly higher among smokeless tobacco users than among either nonusers or smokers.[10] This difference was not significant at younger ages but became obvious in subjects older than 45 years. Smokers had the lowest prevalence of hypertension, as has been found in many other epidemiological studies.[22,25,26] The significantly higher prevalence of hypertension found among smokeless tobacco users, compared with cigarette smokers, could reflect differences in the pharmacodynamic effects of nicotine in smokeless tobacco users and smokers. The use of smokeless tobacco yields high blood concentrations of nicotine and more prolonged and more perpetual levels than smoking. These high concentrations might be accompanied by longer periods of cutaneous vasoconstriction, systemic venoconstriction, and increased muscle blood flow in smokeless tobacco users,[27] and it could be speculated that such mechanisms are more operative for the development of hypertension in smokeless tobacco users than in smokers.

The construction industry demands a high level of physical performance. Persons with decreased capacity are not hired or leave the industry; therefore, construction workers are physically fitter than average citizens of the same age. Because the study sample was drawn from active workers and not from company lists, which might include retired workers, the healthy worker selection could be expected to be more obvious among the workers who belonged to the higher age group at entry into the study. This situation could explain the more pronounced excess risk of cardiovascular mortality found among the younger tobacco users than among the older tobacco users in relation to nonusers in the same age group.

Since smoking—and probably also the use of smokeless tobacco—affects the cardiovascular system in an unfavorable way and leads to poorer physical performance, the above-mentioned selection process may also be related to tobacco habit, probably resulting in an underestimation of the strength of the relationship between tobacco use and cardiovascular mortality.

The results of this study support the hypothesis that smokeless tobacco users face a higher risk than nonusers of dying of ischemic heart disease and cerebrovascular disorders. Smokers still seem to be at the highest risk, and quitting smoking

considerably reduces the risk of cardiovascular events. Even though nicotine is the main substance common to both smokers and smokeless tobacco users, it remains to be elucidated in clinical studies and by laboratory experiments whether the higher risk of cardiovascular disease in smokeless tobacco users is caused by nicotine or by some other exposure related to smokeless tobacco. Data on vasoconstriction, arrythmias, release of stress hormones, atherogenic effects, or hypertension caused by the exposure to nicotine in smokeless tobacco might elucidate this matter. The higher risk of dying of cardiovascular disease in smokers than in smokeless tobacco users supports the idea that there are substances in tobacco smoke other than nicotine that are hazardous. Although the risk of dying of cardiovascular disease is lower for smokeless tobacco users than for smokers, the excess risks are sufficiently impressive to call for action to be taken against the use of smokeless tobacco. □

Urinary Tract Infection during Pregnancy: Its Association with Maternal Morbidity and Perinatal Outcome

Laura A. Schieve, MS, Arden Handler, DrPH, Ronald Hershow, MD, Victoria Persky, MD, and Faith Davis, PhD

ABSTRACT

Objectives. **The effects of antepartum urinary tract infection on adverse maternal and perinatal outcomes were examined. Antepartum urinary tract infection has been previously implicated as a risk factor for numerous outcomes.**

Methods. **Crude and multivariable analyses were performed with a perinatal registry cohort of 25 746 mother/infant pairs.**

Results. **Elevated risks were observed for exposure to urinary tract infection and low birthweight, prematurity, preterm low birthweight, premature labor, hypertension/preeclampsia, maternal anemia, and amnionitis. Urinary tract infection was associated with perinatal death only among subjects 20 to 29 years of age.**

Conclusions. **These findings underscore the importance of antepartum urine screening to identify patients at risk for adverse outcomes. (*Am J Public Health.* 1994;84: 405–410)**

Introduction

Despite a plethora of research since Kass first noted an association between untreated urinary tract infection and perinatal mortality in 1962,[1] the extent to which antepartum urinary tract infection affects maternal and perinatal health remains ambiguous. At present, the only certain conclusion is that the risk of progression to pyelonephritis greatly increases during pregnancy, with rates as high as 30% reported among untreated women.[1–7]

Antepartum urinary tract infection has also been implicated as a risk factor for adverse perinatal outcomes—premature birth and/or low birthweight[1,3–5,7–14] and perinatal death[1,4,9]—in numerous observational studies. However, an equal number of negative findings have been reported.[2,6,15–28] Results of clinical trials examining the effect of antibiotic treatment on reducing the risk of low birthweight have been inconsistent as well.[1,3,4,7,9,10] In addition, associations have been documented between antepartum urinary tract infection and a variety of maternal complications of pregnancy, including hypertension/preeclampsia,[4,5,7,8,17] anemia,[8,9,15,22] amnionitis,[21] and endometritis.[29] The causal nature of these associations is questionable, because it is not always clear whether an episode of urinary tract infection preceded the particular outcome of interest, especially in regard to maternal hypertension and anemia. Although the definitions of these outcomes in many studies render it difficult to determine the proper sequence of events, a temporal relationship between urinary tract infection and hypertension was clearly established by Stuart et al.,[5] and a temporal relationship between urinary tract infection and anemia was established by Brumfitt.[9] These results support possible causal relationships. As with the perinatal outcomes, many investigators have also failed to demonstrate any effect with urinary tract infection and maternal outcomes.[2,6,11,16,20,24,27] Limited sample sizes and inadequate control of confounders may partially explain the discrepancy in findings to date.

This study used registry data to examine associations between antepartum urinary tract infection and adverse maternal and perinatal outcomes independent of other possible risk factors. The large sample size afforded by the registry also provided an opportunity to evaluate possible mechanisms through which urinary tract infection might exert an effect on pregnancy outcome.

Methods

We performed a retrospective cohort analysis with data from the University of Illinois Perinatal Network database, a registry of more than 150 000 obstetric events occurring from 1983 through 1989 in 14 hospitals in the Chicago area. Trained personnel abstracted more than 450 maternal, fetal, and neonatal variables from patients' medical records upon completion of pregnancy. We limited our analysis to 1988 and 1989 because of changes in abstracting format. We also limited the analysis to the four hospitals with the

This paper was accepted June 2, 1993.

largest obstetric populations to allow a feasible reabstraction of a subset of records, in order to assess the exposure classification more thoroughly. All singleton live births and fetal deaths were included, with the exception of 115 subjects for whom information on urinary tract infection was not recorded (0.4% of the sample). In all, 25 746 women were included in this analysis; 1988 (7.7%) were considered positive for antepartum urinary tract infection and constituted the exposure group. The remainder constituted the nonexposed group.

Classification of urinary tract infection was based on (1) a positive urine culture during the antepartum period, as noted by a health care provider and recorded in the medical record, or (2) a diagnosis of urinary tract infection and/or pyelonephritis during the antepartum period recorded in the medical record. This allowed inclusion of cases of urinary tract infection diagnosed by a variety of methods, including culture, rapid-screening techniques, and clinical presentation. In most cases, it was not possible to discern the way in which a diagnosis was made from the information provided in the record. Our definition of urinary tract infection encompassed both asymptomatic and symptomatic infections because it included those individuals for whom a positive culture was recorded without a stated diagnosis of urinary tract infection. However, we were unable to determine the proportion of our exposed group that was symptomatic from the information provided.

The perinatal outcomes examined in this study include perinatal death (fetal death or neonatal death within the first 28 days of life, providing that the infant had not been discharged from the hospital), low birthweight (2500 g or lower) prematurity (less than 37 weeks gestation), preterm low birthweight (2500 g or lower *and* less than 37 weeks gestation), and small for gestational age (birthweight less than the 10th percentile of the birthweight distribution of the singleton deliveries in the database at each gestational age and infant sex).

Maternal outcomes evaluated include premature labor (onset of labor prior to 37 weeks of gestation, even if the episode was resolved and the pregnancy went to term), hypertension/preeclampsia (diagnosis of pregnancy-induced hypertension or preeclampsia specified by a health care provider), anemia (hematocrit less than 30%), amnionitis (diagnosis of amnionitis, chorioamnionitis, membranitis, or placentitis), and endometritis (diagnosis of endometritis or endomyometritis).[3] Because the exact timing of maternal complications was not recorded for this data set, it is unknown whether an episode of urinary tract infection actually preceded each of these outcomes. Therefore, this study is actually cross-sectional with respect to the maternal outcomes.

Because sexual intercourse is a risk factor for both urinary tract and genital tract infections and since genital tract infections may also be associated with adverse reproductive outcome, the detection of one or more genital tract pathogens during the antepartum period (syphilis, gonorrhea, genital herpes, condyloma, chlamydia, Beta Streptococcus vaginal infection, *Candida albicans*, *Trichomonas vaginalis*, *Gardnerella vaginalis*, unspecified vaginitis or cervicitis) was treated as a potential confounder in this analysis. Since ascertainment of antepartum urinary tract infection may have varied by hospital, odds ratios were also adjusted for hospital of delivery. Other variables evaluated as potential confounders include age (<20, 20 through 29, ≥30 years), race/ethnicity (White/Asian/other, Black, Hispanic), and prior pregnancy history. Pregnancy history was classified as follows: (1) primigravida, (2) at least one pregnancy ending in adverse outcome (congenital anomaly; fetal, neonatal, or postneonatal death; ectopic pregnancy or hydatid mole; spontaneous abortion; premature birth; or term birth with intrauterine growth retardation), (3) at least one pregnancy ending in induced abortion and no others ending in adverse outcomes or (4) all pregnancies ending in healthy outcomes (term births with no congenital anomalies or growth retardation).

Odds ratios (ORs) and 95% test-based confidence intervals (CIs) were computed for exposure to antepartum urinary tract infection and all perinatal and maternal outcomes. Mantel-Haenszel adjusted odds ratios were estimated from stratified analyses of all associations controlling for each of the potential confounders individually.[30] These summary estimates were evaluated with Breslow-Day tests of homogeneity.

Unconditional logistic regression was used to simultaneously adjust for age, race, prior pregnancy history, hospital of delivery (A, B, C, or D), and antepartum genital tract infection for each outcome. In addition, because univariate analysis revealed that the risk estimate for urinary tract infection and perinatal death was not homogeneous with respect to age, urinary tract infection and age interaction terms were entered into the model with perinatal death. Odds ratios were calculated from beta coefficients, and 95% confidence intervals were calculated from the respective standard errors.[31]

Because any association between urinary tract infection and adverse reproductive outcome may vary by the severity of infection, we repeated our analysis after subdividing the exposure group by progression to pyelonephritis. This analysis is presented only for the perinatal outcomes, however, since the number of subjects with both pyelonephritis and one of the maternal outcomes under study was very small and odds ratios were difficult to interpret. The relationship between the timing of infection and each outcome variable would also be of interest. Unfortunately, the data to address this issue were not available.

We also explored possible mechanisms by which urinary tract infection might affect perinatal outcome. Hypertension, anemia, and amnionitis were evaluated as possible intermediaries in the association between urinary tract infection and adverse perinatal outcome, because each of these conditions has been previously implicated as a consequence of antepartum urinary tract infection[4,5,7–9,15,17,21,22] and a risk factor for adverse perinatal outcome.[32–35] These analyses were limited to preterm low birthweight, the outcome with which urinary tract infection appeared most strongly associated, because any effect would be most likely with this association. We repeated both crude and multivariable analyses, excluding subjects with each of the postulated intermediary variables to assess whether the associations persisted in their absence.

Finally, in an effort to discern whether urinary tract infection per se is a risk factor for preterm low birthweight or whether the infectious process in general creates risk, the effect of urinary tract infection was compared with other infections commonly acquired by women of childbearing age, specifically genital and upper respiratory tract infections. The study population was divided into five mutually exclusive exposure groups: urinary tract infection only, genital tract infection only, upper respiratory tract

infection only, multiple infections (more than one of these three infections), and none of these infections. Odds ratios were calculated for each exposure group and preterm low birthweight, with the no infection group as the reference category.

Results

As shown in Table 1, the exposure groups were not homogeneous with respect to the potential confounding variables under study. Subjects classified in the urinary tract infection category were more likely than those in the nonexposed group to be non-White, to be younger, to have delivered at hospital D, and to have had an antepartum genital tract infection. They were less likely to have had a prior pregnancy that ended in a healthy outcome.

Women exposed to antepartum urinary tract infection were found to be at greater risk (unadjusted) of delivering infants with low birthweights, premature infants, preterm infants with low birthweights, and infants small for gestational age than those who were not exposed (Table 2). They were also more likely to experience premature labor, hypertension/preeclampsia, anemia, and amnionitis during pregnancy. Although the perinatal mortality and endometritis rates were higher among the exposure group, these differences did not reach statistical significance.

The risk of urinary tract infection on adverse perinatal outcomes was greatest among those with the most severe infection, pyelonephritis (Table 3). However, because only a small percentage of subjects (8.1%) progressed to pyelonephritis, the odds ratios after excluding these subjects from the exposure group were virtually the same as when exposure was defined as both pyelonephritis and nonpyelonephritis cases of urinary tract infection combined.

After single-factor adjustment for age, race, hospital of delivery, prior pregnancy history, and genital tract infections, all statistically significant associations in the crude analysis, with the exception of the urinary tract infection–small for gestational age association, remained elevated (data not shown). A significant association was also found between urinary tract infection and perinatal death when maternal age was between 20 and 29 years.

Multivariable adjustment reduced the risk estimates, but the associations between antepartum urinary tract infection and low birthweight, prematurity, preterm low birthweight, premature labor, hypertension, anemia, and amnionitis remained statistically significant (Table 4). As in the univariate analysis, the small for gestational age adjusted odds ratio was not significant, and the adjusted odds ratio for perinatal death was significant only for those 20 to 29 years old.

Neither the crude nor the adjusted odds ratio was modified when hypertension, anemia, or amnionitis cases were deleted from the urinary tract infection–preterm low birthweight analyses (adjusted OR excluding hypertension = 1.4, 95% CI = 1.2, 1.7; adjusted OR excluding anemia = 1.5, 95% CI = 1.2, 1.8; adjusted OR excluding amnionitis = 1.4, 95% CI = 1.1, 1.7). The risk of preterm low birthweight was virtually the same for women with an antepartum urinary tract infection only, an antepartum genital tract infection only, or both types of infection (Table 5). (Because of the unstable estimates from the multivariable analyses, only the unadjusted estimates are presented.) Women exposed to upper respiratory tract infection only were at no greater risk of delivering preterm low-birthweight infants than were those in the "infection-free" group.

TABLE 1—Selected Characteristics of Study Subjects, by Exposure to Antepartum Urinary Tract Infection

Characteristic	Exposed (n = 1988), %	Nonexposed (n = 23 758), %
Race*		
White/Asian/other	28.7	47.0
Black	30.1	17.8
Hispanic	41.1	35.3
Age*

Previous adverse outcome	27.4	24.0
Induced abortion (no adverse outcome)	11.9	10.0
All healthy outcomes	30.0	36.7
Genital tract infection*	21.2	11.3

*P < .001 by chi-square test for proportional differences for comparison between exposure groups.

Discussion

We found that women who acquire urinary tract infections during pregnancy are at increased risk of delivering low-birthweight, premature, and preterm low-birthweight infants. Our odds ratios of 1.4 for low birthweight, 1.3 for prematurity, and 1.5 for preterm low birthweight compare well with a recent meta-analysis of exposure to antepartum urinary tract infection that reported typical relative risks of 1.5 and 2.0 for associations with low birthweight and prematurity, respectively.[36] Antepartum urinary tract infection was not associated with delivering infants small for gestational age after multivariable adjustment for potential confounding variables, suggesting that urinary tract infection affects low birthweight through premature delivery rather than growth retardation. This is further illustrated by the relatively strong association between urinary tract infection and premature labor. Antepartum urinary tract infection was also found to be associated with increased maternal morbidity (hypertension, anemia, and amnionitis).

An association between urinary tract infection and perinatal death was found only among the 20- to 29-year-olds. One plausible explanation is that younger

and older women are exposed to multiple competing risks for adverse outcomes—low socioeconomic status and related factors among the younger age group and biological factors among the older age group—which masks the impact of urinary tract infection.[37]

While several previous investigations have found comparable results, they have suffered from small sample sizes and were not adequately able to control for confounding. Of particular interest is whether the effects of urinary tract infection are independent of other infections with similar risk factors for acquisition, such as sexually transmitted diseases. We were able to adjust for antepartum sexually transmitted diseases and other genital tract pathogens in our analysis and did not find any change in the odds ratios. In addition, urinary tract infection and genital tract infection appear to have had similar effects on preterm low birthweight, as evidenced by the comparable odds ratios, when each type of infection was evaluated individually. However, we did not distinguish the genital infection category by specific pathogens. Our analysis also shows that the associations observed between urinary tract infection and both adverse perinatal outcome and maternal morbidity were not due to confounding by age, race, prior pregnancy history, or hospital of delivery.

A major weakness of this study is the method of exposure ascertainment. While most prior investigations have been conducted prospectively, with urine cultures on all women under investigation available to classify urinary tract infection, this study relied on a positive culture result or physician diagnosis of urinary tract infection and/or pyelonephritis in the medical record. This retrospective classification of urinary tract infection raised a number of concerns about the validity and reliability of this variable. Although it was impossible for us to assess validity directly, we reabstracted a random sample of charts from our study population to evaluate the reliability of the original abstraction process and to provide some sense of potential limitations of the urinary tract infection variable beyond abstraction error. In all, 217 charts were reabstracted, 112 from the exposed group (5%) and 105 from the nonexposed group (0.4%).

Agreement between this second abstraction and the original classification of urinary tract infection in the database was 96.2% for the nonexposed group but only 69.6% for the exposure group. (That is, 30.4% of our exposure group was not reclassified as having a urinary tract infection, during the second abstraction.) Further evaluation of these apparently misclassified subjects revealed that the incidence of adverse outcomes was lower in this group than for those classified correctly as having a

TABLE 4—Adjusted Odds Ratios for Exposure to Antepartum Urinary Tract Infection and Selected Perinatal and Maternal Outcomes

Outcome	Odds Ratio	95% Confidence Interval
Perinatal		
Perinatal death		
Age < 20 d	0.3	0.1, 1.3

URI and genital infection	194	1.2	0.6, 2.3
All 3 infections	24	0.9	0.1, 6.1

urinary tract infection. Therefore, including these subjects in the exposure group biased our results toward the null hypothesis, and the true associations are likely to be stronger than our estimates indicate.

In addition to abstraction quality, the classification of urinary tract infection used in this study is subject to a number of other potential shortcomings. First, if a woman did not receive prenatal care, an episode of urinary tract infection may have occurred during pregnancy that went unrecorded. In addition, even if a woman did receive prenatal care, her prenatal care record may not have been incorporated into her hospital of delivery medical record, potentially resulting in a missed case of urinary tract infection. Our reabstraction revealed that 13.4% of our study population did not receive prenatal care and that the prenatal care record was unavailable for an additional 4.8%.

In addition to receipt of prenatal care, we were also concerned about the prevalence of laboratory screening for urinary tract infection. Although most prenatal care regimes include an antepartum urinalysis, not all routinely incorporate urine cultures. We found that antepartum urine cultures were recorded for only 33.2% of our reabstracted sample. This is most likely an underestimate, because it is feasible that urine cultures performed during the antepartum period were not always recorded in the medical record. However, it is still cause for concern, since urinary tract infection may be asymptomatic and urinalysis alone may be insensitive. Although these data suggest that cases of asymptomatic urinary tract infection may have gone undetected in this population, any consequent bias would again be toward the null hypothesis because comparison groups would be more homogeneous on exposure.

Given the potential errors in classification, it is encouraging to note that the prevalence of urinary tract infection at each hospital under study fell within the 2% to 10% range seen in other investigations.[1,3,5,6,12,15,26] This rate was actually exceeded at one hospital that serves a large number of indigent women, an observation also consistent with current literature.

Although the registry does not contain information on antibiotic treatment for urinary tract infection, we found, during our reabstraction, that antibiotics were prescribed for 84.6% of those correctly classified as having such an infection, indicating that the exposure group involves mainly treated cases.

Assuming that the association between urinary tract infection and prematurity is real, the mechanism by which the former might exert such an effect is not well established. Several investigators have demonstrated a high incidence (up to 50%) of pyelographic abnormalities, indicative of chronic pyelonephritis, in bacteriuric women.[4,38] It is plausible, then, that the effect of urinary tract infection on premature birth could be indirectly mediated by occult renal abnormalities that result in antepartum maternal complications such as hypertension/preeclampsia or anemia. Our data do not support this hypothesis, because no change in the odds ratio was observed for the association between urinary tract infection and preterm low birthweight when women with either hypertension or anemia were excluded from analysis. We cannot eliminate other possible effects of renal abnormalities, however.

It is also conceivable that urinary tract infection affects premature labor directly, through the development of amnionitis. It has been previously suggested that bacterial infection of the amniotic fluid is a risk factor for premature delivery.[34,35] One hypothesis contends that bacterial enzymes such as collagenase may weaken the fetal membranes and predispose them to rupture, which subsequently triggers the onset of labor.[39] It has also been postulated that bacterial products such as phospholipase A and C or endotoxins may stimulate prostaglandin biosynthesis by the fetal membranes, which then initiates labor.[40] Alternatively, these bacterial products might stimulate the patient's immune system, causing the release of monokines (particularly Platelet Activating Factor, Interleukin-1, and Tumor Necrosis Factor) that then trigger prostaglandin production.[40] It has also been demonstrated that bacteriuric women may subsequently develop an amniotic fluid

infection with the same organisms commonly isolated from urine specimens, namely coliform bacteria such as *Escherichia coli*.[21] We found no change in the odds ratio after deleting cases of amnionitis, although subclinical amniotic infection has been repeatedly documented[41-43] and may have been a latent causative factor in this population.

Future studies are needed to address the interrelationship between urinary tract infection, amnionitis, and premature labor. Ideally, these associations should be explored in a prospective study with well-defined criteria for both exposure and outcome variables.

Although the mechanism remains unclear, these data, along with prior investigations, indicate that antepartum urinary tract infection indeed affects both maternal and perinatal health, even when treated. Early prenatal screening of women for urinary tract infection and treatment of women found to be bacteriuric are already indicated to prevent progression to pyelonephritis. The associations documented here provide further compelling support for screening to identify patients at risk for adverse pregnancy outcomes. □

Acknowledgments

We are grateful to the University of Illinois Perinatal Management Group for allowing us access to the database. In addition, we would like to thank Deborah Rosenberg and Cynthia Ferre for their assistance with computer programming and Susan Ataman, Susan Johnson, and Edna Brooks for their help with data collection.

Maternal Attitude toward Pregnancy and the Risk of Neonatal Death

Muhammad N. Bustan, MD, DrPH, and Ann L. Coker, PhD

ABSTRACT

Objectives. **Reduced options for fertility control over the past decade have increased the rates of unwanted pregnancy. We evaluated whether a woman's negative attitude toward her pregnancy increased the risk of perinatal mortality, in a large, prospective cohort study.**

Methods. **The association between attitude toward the pregnancy and perinatal mortality was evaluated in a longitudinal cohort study of 8823 married, pregnant patients enrolled from 1959 to 1966 in the Child Health and Development Studies.**

Results. **Women who reported during the first trimester of prenatal care that the pregnancy was unwanted were more than two times more likely to deliver infants who died within the first 28 days of life than were women reporting accepted pregnancies. A positive attitude toward pregnancy was not associated with fetal death or postneonatal death.**

Conclusions. **These data, collected when induced abortions were illegal, may have important implications for the 1990s. If maternal attitude toward the pregnancy is associated with neonatal mortality and abortion laws change such that access is restricted, infant mortality may increase because a greater proportion of births will be unwanted. (*Am J Public Health.* 1994; 84:411–414)**

Introduction

In 1973, the year of the *Roe v Wade* Supreme Court decision (410 US 113) that made abortion legal in the United States, 14.3% of pregnancies were reported by respondents to the National Survey of Family Growth as unwanted at conception.[1] Almost 10 years later, in 1982, the percentage of pregnancies reported as unwanted at conception fell to almost one half the 1973 percentage (7.7%). However, during the late 1980s, when abortion remained legal but politically and legally challenged, the percentage of women reporting pregnancies as unwanted increased to 10.3%.[1] Given this trend toward increasing numbers of unwanted pregnancies, particularly if abortion becomes inaccessible in the United States, further attention must be given to the consequences of unwanted childbearing.

Being unwanted puts children at increased risk of a range of adverse health outcomes, including child abuse[2] and delayed cognitive and social-emotional development.[3–5] Women with unwanted pregnancies are less likely to seek early and adequate prenatal care[6–8] and may thus be at increased risk of delivering infants with adverse pregnancy outcomes. In a Finnish study, women reporting infants unwanted at birth were more likely to have infants of lower birthweights and higher rates of infant mortality.[9] Kafatos and Pantelakis reported that being illegitimate or unwanted was a risk factor for perinatal morbidity and mortality.[10]

No US-based study of pregnancy attitude and perinatal mortality has assessed attitude early in the pregnancy and followed women to delivery to ascertain pregnancy outcomes. This analysis of the Child Health and Developmental Studies cohort (recruited from 1959 to 1965) assessed attitude toward the pregnancy at the first prenatal care visit and followed these Kaiser Health Plan patients to delivery. The risk of fetal, neonatal, and postneonatal mortality associated with being unwanted was estimated while controlling for important confounders, including level of prenatal care.

Methods

The Child Health and Development Studies involved a prospective cohort of 20 754 pregnancies to women who were members of the Kaiser Health Plan in the East Bay Area of San Francisco between June 1959 and September 1966.[11] Women attending Kaiser clinics for confirmation of pregnancy were asked to participate. Pregnant women were then followed throughout their pregnancy while receiving prenatal care in Kaiser clinics. Those who changed care providers during the pregnancy or delivered at facilities other than Kaiser's were dropped from the follow-up. Subsets of children were followed for up to 15 years.

During the pregnancy follow-up periods, information from several sources was collected. Women were to be interviewed early in their pregnancies to

This paper was accepted June 29, 1993.

obtain information on their medical history; behavioral risk factors, including tobacco and alcohol intake; and sociodemographic factors. Also, the women and their husbands were asked about their attitude toward the pregnancy. Existing medical records were computerized and linked with the mother's personal interview, including the prenatal care record, and the mother's and infant's hospital records.

For the purposes of this analysis, women who were unmarried, who were interviewed after delivery, or who did not answer the question on attitude toward the pregnancy were excluded. In addition, to address the issue of nonindependence of pregnancy outcomes with the same mother, only one randomly selected pregnancy per woman was included in this analysis, leaving a total of 8823 eligible married women 20 to 50 years old.

Attitude toward the pregnancy was classified on the basis of the woman's response to a question asked during the first trimester of pregnancy about her perception and that of her husband in regard to their pregnancy. If the woman indicated that either she or her husband was unhappy, resentful, or upset about the pregnancy or did not want the pregnancy or that the pregnancy was mistimed, the pregnancy was categorized as unwanted. If they indicated that they were happy about the pregnancy or stated that they wanted, accepted, or planned the pregnancy, the pregnancy was categorized as accepted. Women who reported that they or their husband had contradictory feelings about the pregnancy were not included in either group for this analysis. Changes in attitudes during pregnancy were not considered.

Information regarding fetal, neonatal, and postneonatal death was obtained from medical records and autopsy reports. A fetal death was defined as fetal loss prior to delivery and included stillbirths as well as recognized early pregnancy loss. A neonatal death was defined as a live-born baby who expired within 28 days of birth, while a postneonatal death was defined to include live-born infants dying after the 28th day of life but prior to 1 year of age.[12] The specific cause of death was not noted.

Information on the following risk factors was available from data collected for this cohort of women: maternal and paternal age, race, educational attainment, religion, family income, parity, interpregnancy interval, maternal and paternal smoking and drinking exposure, infant birthweight, and the presence of a congenital anomaly in the infant. These data were used to identify factors that may confound the relationship between being unwanted and infant mortality (fetal, neonatal, and postneonatal mortality). Factors associated with attitude toward the pregnancy were first described by comparing the proportion of those reporting an unwanted pregnancy with the selected risk factors and the proportion of those reporting an accepted pregnancy. Similarly, risk factors for neonatal mortality were assessed by comparing the proportion of those experiencing neonatal mortality with the selected risk factors and the proportion among live-born and surviving infants. Factors associated with both attitude toward the pregnancy and neonatal mortality (confounders)[13] were included in logistic regression models estimating the risk of infant death associated with being unwanted.

Results

Of the 8823 married, pregnant Kaiser patients enrolled in the study and included in this analysis, 1274 (14.4%) reported that the pregnancy was unwanted when asked during the first trimester. Several factors were associated with reporting the pregnancy as unwanted vs wanted. In comparison with women reporting the pregnancy as accepted, women reporting that the pregnancy was unwanted were 2.9 times more likely (95% confidence interval [CI] = 2.2, 3.7) to be 40 years of age or older, twice as likely (95% CI = 1.7, 2.3) to have husbands with less than a high school education, and 3.7 times more likely (95% CI = 3.1, 4.4) to have had four or more children. Women reporting an unwanted pregnancy were 40% more likely (odds ratio [OR] = 1.4, 95% CI = 1.3, 1.6) to be non-White and 20% more likely (OR = 1.2, 95% CI = 1.0, 1.4) to be smokers. Reporting an unwanted pregnancy was not associated with the infant having had any congenital anomaly (OR = 1.0, 95% CI = 0.7, 1.4), with having a short interpregnancy interval among parous women (OR = 0.9, 95% CI = 0.8, 1.1), or with low infant birthweight (OR = 1.1, 95% CI = 0.9, 1.4). In addition, maternal education, paternal age, and paternal race were not independently associated with attitude toward the pregnancy (when controlling for paternal education, maternal age, and race).

Although information was collected on other potential confounders, sufficiently large numbers of missing values precluded the use of family income (10% missing), religion (30% missing), and maternal and paternal alcohol consumption (15% missing).

Of the cohort of 8823 live births, 83 infants (0.9%) died within the first 28 days of life (neonatal deaths) and 57 (0.6%) died after the first 28 days but prior to 1 year of age (postneonatal deaths). Three hundred thirty-one fetal deaths (3.8%) were observed in this cohort of pregnancies. Risk of neonatal death increased with decreasing educational level of the husband (OR = 1.9 for less than a high school education, 95% CI = 0.9, 3.7) and with increasing parity (OR = 2.4 for parity of four or more, 95% CI = 1.2, 4.5). As expected, low birthweight (< 2500 g) was strongly associated with neonatal death (OR = 39.6, 95% CI = 29.6, 52.9), as was having any congenital anomaly (OR = 10.7, 95% CI = 7.2, 15.9). Women 40 years of age or older appeared to be at a slightly reduced risk of having a child who died prior to 28 days, but the confidence interval for this estimate was wide (OR = 0.4, 95% CI = 0.02, 2.58). Maternal race, interpregnancy interval, and smoking during pregnancy were not consistently associated with neonatal death. Also, maternal education, paternal age, and paternal race were not independently associated with neonatal death.

Table 1 presents the number and percentage of unwanted and accepted pregnancies by the following pregnancy outcome categories: fetal death, neonatal death, postneonatal death, and live-born infants surviving beyond 1 year of age (n = 8740). Crude and adjusted relative risk estimates for pregnancy attitude and the perinatal mortality outcomes obtained from multiple logistic regression are also presented in Table 1. Only neonatal death was significantly associated with being unwanted. Women reporting, during the first trimester of prenatal care, that the pregnancy was not wanted were 2.4 times more likely (95% CI = 1.5, 4.0) to deliver infants who died within the first 28 days of life. The crude relative risk estimate for this relationship was 2.7 (95% CI = 1.8, 4.2). Women reporting their pregnancy as unwanted were no more likely to have the pregnancy end in a

fetal death (adjusted OR = 1.1, 95% CI = 0.9, 1.5) than were women accepting their pregnancies. Postneonatal death was not associated with attitude toward the pregnancy; the adjusted relative risk estimate was 0.9 (95% CI = 0.5, 1.9).

TABLE 1—Relative Risks for the Relationship between Maternal Attitude toward the Pregnancy and Perinatal and Infant Death

	Unwanted Pregnancy		Accepted Pregnancy		Crude RR (95% CI)	Adjusted RR[a] (95% CI)
	No.	%	No.	%

Discussion

Parents (either the mother or father) perceiving their pregnancy as unwanted had a greater than twofold increased risk of delivering a child who died within the first 28 days of life. Attitude toward the pregnancy was not associated with an increased risk of fetal death or with an increased risk of postneonatal mortality.

Few studies have directly addressed the relationship between pregnancy attitude and infant mortality,[9,10] and none have assessed attitude early in the pregnancy and followed women to determine subsequent pregnancy outcomes. Kafatos and Pantelakis[10] did find a significant association between illegitimacy and perinatal mortality, while Myrhman[9] found that being unwanted increased the risk of low birthweight but not perinatal mortality.

Women enrolled in the Child Health and Development Studies were a select group with unique characteristics that placed them at a reduced risk of adverse pregnancy outcomes. Since all women received early prenatal care, lack of access to such care cannot explain the observed relationship between attitude toward the pregnancy and neonatal mortality. All women in this cohort were married and were either employed or married to men whose employment guaranteed the Kaiser Health Plan. Therefore, the proportion of women who reported unwanted pregnancies in this cohort was probably lower than in a general population of pregnant women. In comparison with a population having less access to prenatal care, this cohort was at reduced risk of adverse pregnancy outcomes, including neonatal mortality.

In the 1990s, relative to the 1960s when these data were collected, significant improvements in survival rates for high-risk, primarily low-birthweight infants have been achieved. In the data reported here, being unwanted was not associated with low birthweight (OR = 1.1); thus, the observed association between attitude toward the pregnancy and infant mortality should still be applicable for pregnancies in the 1990s.

Our finding of no association between attitude toward the pregnancy and postneonatal mortality is somewhat puzzling. However, because the cause of death was not coded, we cannot, for example, look at the relationship between pregnancy attitude and intentional injury, nor can we correlate time of death with its cause by pregnancy attitude. Since this is one of the first studies to report an increased risk of neonatal death associated with being unwanted, additional cohort studies should be conducted in an attempt to replicate these findings.

The definition of an unwanted pregnancy used in this analysis differed from those used in other surveys[14] and may be less biased because women were asked about their feelings regarding the pregnancy at least 6 months prior to delivery. In addition, the question addressed both the woman's and her husband's perceptions of the pregnancy (illegitimate births were not included). Finally, women were allowed a range of responses to this question characterizing their feeling about the pregnancy; pregnancy attitude was not asked as part of the question but was included as a response option.

During the time that women were enrolled in this study (1959 to 1966), abortion was illegal and contraception was not widely available. In light of current political challenges to abortion and family planning, these data may have a particularly important message. If access to abortion and family planning is limited or eliminated, the proportion of women delivering unwanted infants will increase dramatically. If pregnancy attitude is linked to neonatal death and the proportion of unwanted infants increases, then rates of infant mortality may also increase. Since the women included in the analysis were primarily middle income and received early prenatal care and were thus at reduced risk of adverse pregnancy outcomes, the impact of being unwanted on infant mortality may be underestimated. Thus, if these results are applied to women without prenatal care, the magnitude of the effect of attitude toward the pregnancy on infant mortality may be greater.

Pragmatically, reducing the proportion of infants born unwanted is a public health issue that we know how to and have had success in addressing. Public health interventions (family planning and abortion services) do exist to increase the proportion of wanted births and, thus, improve a range of infant health outcomes. □

Women's Health Conference to Be Held in May

The American Psychological Association will hold a conference entitled "Psychosocial and Behavioral Factors in Women's Health: Creating an Agenda for the 21st Century" May 12 through May 14, 1994, at the Capitol Hill Hyatt Regency Hotel, Washington, DC. There will be a preconference awards reception on Capitol Hill on the evening of May 11, 1994, to honor legislators and other key figures in women's health. The goal of the conference is to highlight the importance of psychosocial and behavioral factors in women's health research and the implications for treatment, prevention, and health policy.

Major foci will include theoretical models/frameworks for conceptualizing women's health; issues in research methodology, measurement, and evaluation; new research on psychosocial and behavioral factors in women's health; implications of psychological factors in treatment, health policy, and interventions; and special issues of underserved populations (e.g., ethnic minorities, the poor, women with disabilities, lesbians, and older women). Content areas of interest will include sociocultural influences on health; behavioral and psychosocial risk factors; behavioral and psychosocial factors in health promotion; and coping, resilience, health, and illness.

Registration fees for professionals are $225 (preregistration [received by April 8, 1994]) or $275 (late and on-site registration). Fees for students are $95 (preregistration [received by April 8, 1994]) or $125 (late and on-site registration).

A 6-Year Follow-Up of Behavior and Activity Disorders in the Taiwan Yu-cheng Children

Yung-Cheng Joseph Chen, MD, MPH, Mei-Lin M. Yu, MD, DrPH, Walter J. Rogan, MD, MPH, Beth C. Gladen, PhD, and Chen-Chin Hsu, MD

ABSTRACT

Objectives. **The relationship of behavior and activity levels to the interval between outbreak and year of birth and to age of the children is explored in Taiwanese children exposed in utero to heat-degraded polychlorinated biphenyls (PCBs)—the Yu-cheng children. Additionally, the relationship of the scores to chemical, physical, and cognitive findings is described.**

Methods. **With Rutter's Child Behavior Scale A and a modified Werry-Weiss-Peters Activity Scale, 118 Yu-cheng children and matched controls were followed biannually from 1985 to 1991.**

Results. **At each year, the Yu-cheng children scored 7% to 43% worse (mean = 23%) than control children on the Rutter scale. At any fixed age, the Yu-cheng children scored 11% to 63% (mean = 28%) worse. The effect for children born later did not differ from that for those born earlier; neither was there any improvement as the children aged. A similar but weaker picture was seen for the activity score. These behavioral findings were not related to physical or cognitive findings or to serum PCB levels.**

Conclusions. **In utero exposure to heat-degraded PCBs appears to cause mildly disordered behavior and increased activity level; the effect persists over time and is similar in children born up to 6 years after the mothers were exposed. (*Am J Public Health.* 1994;84: 415–421)**

Introduction

Polychlorinated biphenyls (PCBs), a group of compounds with two linked phenyl rings and various degrees of chlorination, were used widely in industry between the 1930s and 1970s,[1] and have since become ubiquitous and persistent environmental contaminants because of their resistance to chemical and thermal degradation.[2] The most common source of general population exposure is low-level contamination of the food chain; other known sources of exposure, like the workplace or contaminated sport fish, can produce higher body burdens.[3,4] PCBs are readily absorbed when ingested, can persist in fat tissue for years,[5,6] and can cross the placenta to affect the fetus.[7,8] Commercial grade PCBs per se are teratogenic, causing malformations in mice[9] and pigs,[10] and decreased intrauterine growth and survival in monkeys, rabbits, and rats.[11] In utero exposure has also increased motor activity and impaired learning in mice,[12–14] male rats,[15] and rhesus monkeys.[16–18]

Thus far, however, birth defects in human beings have been documented only after maternal exposure to a complex mixture of heat-degraded PCBs. Two such exposures have occurred, one in Japan (called Yusho, or "oil disease") in 1968[19] and one (Yu-cheng, the episode studied here) in Taiwan in 1979.[20] In both instances, PCBs were used as heat exchangers and thus were contaminated by their heat-degraded by-products, polychlorinated dibenzofurans, terphenyls, and quarterphenyls. These chemicals leaked into and became mixed with rice bran oil. Children born to women who had consumed the contaminated oil were found to have ectodermal defects, including hyperpigmentation, deformed nails, and natal teeth; intrauterine growth delay; and developmental delay.[21–23] The Japanese Yusho children were described as hypotonic, apathetic, and dull at 9 and 10 years old.[22]

In the Taiwan incident, more than 2000 people who had consumed the contaminated oil for up to about 9 months between June 1978 and October 1979 were included in the Yu-cheng registry.[20] In the first 3 years after the outbreak, babies born to exposed women had a high infant mortality rate.[20] Surviving children were found to have ectodermal defects, developmental delay, more behavioral problems, and higher activity levels.[23–33] Followed from 1985 to 1991 with cognitive and behavioral tests, these children were also found to have poorer cognitive development up to 7 years of age.[28]

We examine here the behavior and activity level of the children born to exposed women. We explore both the relationship of the behavior and activity scores to the interval between outbreak and year of birth, and the possibility that the effect of exposure diminishes as the children age. We also describe the re-

lationship of the behavior and activity scores to chemical, physical, and cognitive findings.

Methods

Study Subjects

The procedure used to identify the study children has been described in detail elsewhere.[23] Briefly, 132 living children, born to exposed women between June 1978 and February 1985, were identified. These children are referred to as "Yu-cheng children." One hundred and eighteen of them participated in a 6-year cognitive and behavioral follow-up study. For each Yu-cheng child, a control matched on age (within 15 days for those under 1 year, and within 1 month for older children), sex, neighborhood, maternal age (within 3 years), and socioeconomic status was selected for the follow-up study.

Behavioral and Activity Measurement Scales

There was no validated Chinese instrument for assessing children's behavior in 1985. Our group has clinical experience with behavioral disorders in Chinese children, and the items on Rutter's Child Behavior Scale A,[34] which had been validated in British children aged 9 to 12, appeared to be culture fair. The scale is a screening instrument to identify children likely to show some emotional or behavioral disorder; the three sections concern health problems, habits, and behaviors. The questionnaire was modified so that all items allowed a "not applicable" answer, and the parents used this option for younger children in whom one would expect that some of the behaviors asked about could not have occurred. There was a strong relationship between the percentage of not applicable answers and age: 21% for children under age 1, 11% for ages 1 to 2, 4.5% for ages 3 to 4, and less than 1% for ages 5 and over. Chinese parents reported a much higher frequency of behavioral problems in all children, including controls, than one would expect from the results in British children: 48% of the Yu-cheng children and 25.5% of the control children aged 9 to 12 years met Rutter's criterion for a behavioral disorder, compared with 15.1% and 8.1% of the British boys and girls, respectively, of the same ages. Nevertheless, it seemed justified to use the Rutter scale from age 3 years on because less than 5% of the questions were not applicable to children outside the 9- to 12-year age group, and because there were simultaneous control children and so the "normal" values for the instrument did not have to be used. However, it should be borne in mind that it is not known whether these higher scores in the Yu-cheng children, which represent more behavioral problems, are associated with the psychiatric diagnoses with which they are associated in British children. The test-retest reliability was assessed on 30 mothers with a 2-week interval between ratings, and the correlation between the scores on the two occasions was .82.[35]

A modified Werry-Weiss-Peters Activity Scale,[36] which had been validated in Chinese children aged 3 to 11,[37] was used to evaluate the children's activity level. Both behavior and activity questionnaires were filled out by a parent with instructions from an interviewer. The matched control was always evaluated on the same day as the Yu-cheng child. The evaluations were conducted twice a year between fall 1985 and spring 1991, except for spring 1988.

Data Analysis

Paired *t* tests were used to compare the mean Rutter behavior or activity scores between Yu-cheng and control children at each time point or age. Student's *t* tests were used to compare the mean scores of Yu-cheng children who had physical stigmata at birth or in the 1985 survey with the scores of those who did not, and to compare the scores of children who had detectable PCBs with the scores of those who did not. Simple regression analyses were used to test the relationship of the scores to maternal PCB values and IQ score.

Results

One hundred and fifteen of the original 118 Yu-cheng children com-

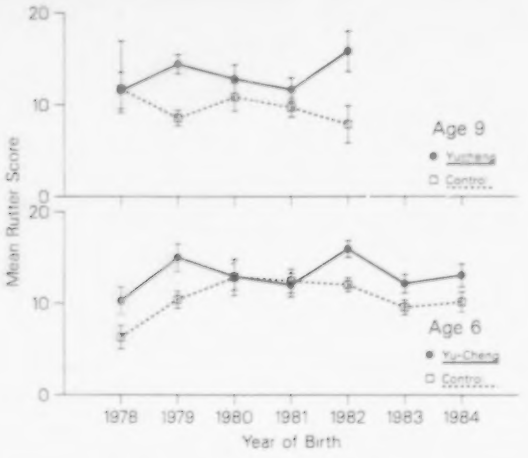

FIGURE 3—Mean Rutter scores at ages 6 and 9 by year of birth, Yu-cheng and control children.

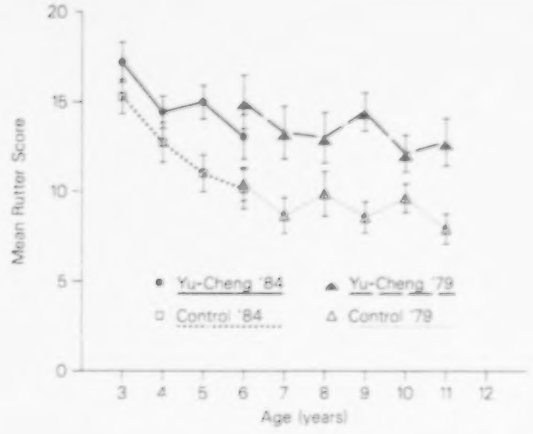

FIGURE 4—Mean Rutter scores for 1979 and 1984 birth cohorts, by age, Yu-cheng and control children.

pleted the 6-year follow-up study, as did their matched controls. The other three Yu-cheng children were removed from the study by their parents in early test rounds, and their corresponding controls were not evaluated further.

Because the children were born over a 7-year period, they were of different ages in any one round of follow-up. When children of different ages were combined and behavior scores analyzed by test time, the Yu-cheng children were found to have scored 7% to 43% (mean = 23%) higher than the control children on the Rutter scale at every time point (Figure 1); all differences were statistically significant except for those in spring 1986 and fall 1987. If analysis was done by age and the scores from different time points were combined, the Yu-cheng children scored 11% to 63% (mean = 28%) higher than their controls at each age (Figure 2); all differences were statistically significant except those for the 12-year-olds, for which there were only 17 pairs.

To examine whether children born longer after the exposure are less affected, the children were separated by year of birth. Figure 3 shows mean Rutter scores for all children aged 6 and 9 arrayed by year of birth. Except for the 1978 birth cohort at age 9 and the 1980 and 1981 birth cohorts at age 6, Yu-cheng children consistently scored higher than their controls. There was no consistent trend toward decreased differences in scores of Yu-cheng and control children as the interval between the exposure and year of birth increased. Pictures at other ages are similar.

To see whether the behavioral abnormality in the children persists as they grow, a given birth cohort was examined over time. The Rutter scores of the 1979 and the 1984 birth cohorts, arrayed by age, are shown in Figure 4. The difference between the Yu-cheng and the control children did not decrease as the children grew older.

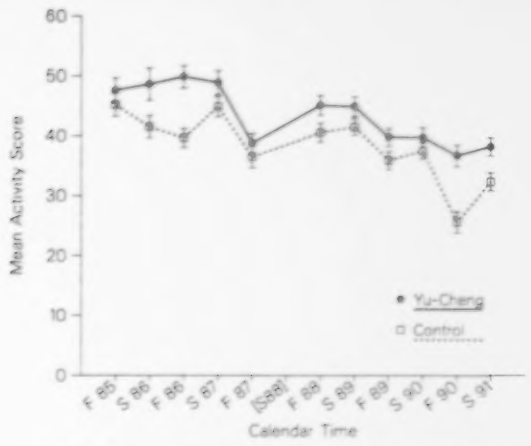
A similar but weaker picture was seen for the activity score. At each round, Yu-cheng children had a mean activity score 5% to 44% higher than the control children (Figure 5), and the differences were statistically significant at seven time points; Yu-cheng children scored 8% to 53% higher than their controls at each age (Figure 6), and the differences were significant in six age groups. The average differences across calendar time or across age were both highly significant.

There is information on physical findings, cognitive scores, and PCB levels of the Yu-cheng children from previous studies.[23,25,28,38] When the Rutter and activity scores of Yu-cheng children with various historical or physical stigmata were compared with the scores of those children without the stigmata, there did not appear to be any consistent trend. Children with physical signs had a higher mean score at some ages and a lower score at others (Table 1). Cognitive scores, PCB detectability, maternal serum PCB levels, and breast-feeding mode did not have consistent relationships to Rutter or activity scores, either.

Discussion

The data show that in utero exposure to PCBs and their heat-degraded contaminants is associated with mildly disordered behavior and increased activity level. The effects persisted as the children aged, and they appeared to be similar in children born up to 6 years after the mother was exposed. This is the first study to report the long-term effects of in utero exposure to heat-degraded PCBs on children's behavior and activity level.

Some of the children still have visible Yu-cheng–related physical stigmata, such as abnormal patterns of pigmentation, hypoplastic nails, and teeth that are very susceptible to caries. Since both the behavior questionnaire and the activity checklist were filled out by a parent, the perception of the parent that his or her child is "abnormal" may contribute to the differences in reported behavior and activity. So far, we have not seen consistent relationships between either cognitive[38] or behavioral function in the children and the presence of the physical stigmata of the syndrome. In general, the physical signs are subtle, and among children old enough to attend school, the results of teacher ratings on each child's maladaptive behavior and activity level are thus far



Note. F = fall, S = spring; activity levels were not evaluated in spring 1988.

consistent with the parent's rating.[26,29,32,33] We believe the teachers are less likely to be aware of the child's exposure status and are thus not sensitized to the child's behavior. It is also possible that the perception that the child is damaged, regardless of whether there are physical signs, may in fact affect a parent's attitude in rearing the child and produce the abnormal behavior.

Yu-cheng children had persistent cognitive deficits up to 7 years of age.[28] The observed association between in utero PCB exposure and persistent behavior and activity level alteration may be secondary to the cognitive developmental delay. Our data did not show consistent and significant associations between cognitive scores and behavioral scores for the Yu-cheng children. This suggests that the developmental delay observed in these children did not produce secondary behavioral problems.

The finding of no consistent relationships between behavior/activity scores and physical findings, cognitive scores, and serum PCB levels is consistent with our previous report,[38] in which we found inconsistent relationships between cognitive developmental scores and physical stigmata and serum PCB levels. It is possible that our measures of dose did not accurately reflect the children's in utero exposure; that the congeners responsible for the physical stigmata may not have been those responsible for the cognitive delay or the disordered behavior; or that different mechanisms were involved in the physical stigmata, cognitive delay, and disordered behavior.

We matched the control children with the Yu-cheng children on age, sex, neighborhood, maternal age, and socioeconomic status. None of the exposed families had any psychiatric history, none of the exposed mothers had ever smoked, and only two exposed mothers had ever drunk regularly. However, other factors that we did not measure could have caused residual confounding; these factors may include parity, temperament of the mother, child-rearing attitudes or behaviors, and family and parental stresses. There is, however, no a priori reason to believe that control families differed in stress levels, attitudes, or illnesses other than those caused by exposure.

The Japanese Yusho children were described as hypotonic, apathetic, and dull at 9 and 10 years old.[22] However, since these children were not randomly selected and no controls were compared, the observation may not represent the whole picture of Yusho children.

Behavior and activity levels were evaluated in two US cohorts—one in Michigan, the other in North Carolina—exposed perinatally to background levels of PCBs. In North Carolina, using the information abstracted from report cards, researchers found no significant relationship between PCB exposure, either prenatally or through breast milk, and the child's work habit or conduct grades.[39] The study also found no association between exposure and hyperactivity reported by parents.[39] In the Michigan study, which used the reports from mothers and examiners when the children were 4 years of age, a composite activity rating was not related to prenatal PCB exposure.[40] The negative results in the two US cohorts were probably due to the low dose of PCBs and the virtual absence of polychlorinated dibenzofurans in the US exposures.

The Michigan study did find reduced activity among children with higher 4-year serum PCB levels.[40] These PCB levels were related to the children's breast-feeding history and not to their prenatal exposure, and the effect was seen only in children who had been breast-fed for more than 1 year and whose mothers had above average breast milk PCB levels. Breast-feeding has the potential to transfer much more of these chemicals to the child than does transplacental exposure. The Michigan findings were consistent with findings from two laboratory studies that found that postnatal exposure to PCBs reduced the activity level.[41–43] In our study, breast-feeding was not found to have a consistent association with the child's activity level among the Yu-cheng children. However, Yu-cheng mothers were advised not to breast-feed their children, and only 30 did.

Behavioral alterations appear in animals exposed perinatally to PCBs.[44]

The most consistent finding has been hyperactivity among animals—namely, mice, male rats, and rhesus monkeys—exposed in utero.[12-18] One group of rhesus monkeys exposed perinatally were hyperactive at 6 and 12 months of age but were hypoactive at 44 months.[16] The authors suggest that the altered behavior was a delayed and possibly permanent effect of the early exposure.

The continued mildly disordered behavior in these children is likely due to the persistence of the chemicals in their mothers, which resulted in the child's in utero exposure long after the mother's exposure to the chemicals ceased. Even though the levels in the mothers were declining, there appeared to be sufficient agent to be toxic for at least 6 years after the exposure. The persistent effect observed as the children aged may have been due to either continued internal exposure to PCBs/polychlorinated dibenzofurans stored in the body or permanent structural changes.

The biological mechanism that causes behavioral toxicity is unclear. It has been suggested that the PCB congeners responsible for neurochemical changes are different from the dioxin-like coplanar congeners that bind the Ah receptor and cause immunotoxicity, enzyme induction, and possible carcinogenesis.[45] After exposure of intact pigtail macaques (*Macaca nemestrina*) to two PCB mixtures, ortho- and ortho-, para-substituted congeners were found in the nigra-striatal system and the hippocampus, and the presence of these congeners correlated with decreases in the dopamine content in these brain regions.[45,46] Thus, these orthosubstituted nonplanar congeners may be responsible for the observed changes in in vivo neurochemistry. This suggestion is supported by the observation that there were no consistent relationships between behavioral scores and physical findings in the Yu-cheng children. One other possible mechanism is that the planar dioxin-like congeners alter brain steroid levels during development, which changes brain organization and the regulation of dopaminergic systems.[45]

The findings of mildly yet persistently disordered behavior and higher activity levels among the Yu-cheng children in this study is of public health significance. Even though PCBs have not been manufactured since the late 1970s, all PCB-containing equipment will have to be disposed of in some way. There will continue to be a risk of exposure to workers and the general population through accidents, improper disposal practices, transport of equipment containing huge amounts of PCBs, and contaminated animals and food. Prenatal exposure can cause activity alteration at a level that does not cause obvious clinical symptoms. The Yu-cheng children are the only well-documented cohort with sufficient in utero exposure to cause obvious toxicity. The behavioral and activity findings from this cohort may help us understand the toxicity that background exposure may cause. We will continue to follow these children and evaluate their health outcomes to understand the disease process. □

Air Recirculation and Sick Building Syndrome: A Blinded Crossover Trial

Jouni J. K. Jaakkola, MD, DSc, Pekka Tuomaala, TechLic, and Olli Seppänen, TechLic

ABSTRACT

Objective. This study tested the hypothesis that recirculated air in mechanically ventilated buildings causes symptoms commonly referred to as the sick building syndrome and perceptions of poor indoor air quality.

Methods. A blinded, four-period crossover trial was carried out in two identical buildings, contrasting 70% return air (index phase) with 0% of return air (reference phase). Each period lasted 1 workweek. The study population comprised 75 workers who had reported symptoms related to the work environment or perceptions of poor indoor air quality. Participants reported their ratings of symptoms, their perceptions, and related information in a daily diary. The outcome criteria included aggregative symptom scores for mucosal irritation, skin reaction, allergic reaction, and general symptoms formed of ratings of component symptoms. Perceptions of unpleasant odor, stuffiness, or dustiness were additional outcome criteria.

Results. All 75 participants returned their diaries. For no symptoms did the scores differ between the two phases more than could be expected by chance. Mean rating of unpleasant odor was significantly smaller during the index phase, but mean ratings of dustiness and stuffiness did not differ materially between the two phases.

Conclusions. Our results suggest that 70% recirculated air, when accompanied by an adequate intake of outdoor air, can be used without causing adverse effects. (*Am J Public Health.* 1994;84:422–428)

Introduction

Office workers in North America and Europe have been reported to have symptoms and other health problems attributed to the work environment.[1–12] These symptoms are nonspecific and occur in any population, but several studies indicate that they are more common among the occupants of certain buildings, often referred to as "sick buildings." Thus, the recurrence of these symptoms has given rise to the concept of the sick building syndrome. According to a World Health Organization working group, this syndrome is characterized by eye, nose, and throat irritation; a sensation of dry mucous membranes and skin; erythema; mental fatigue; headache; a high frequency of airway infections and cough; hoarseness; wheezing, itching, and nonspecific hypersensitivity; nausea, and dizziness.[13] There have been several other attempts to define the syndrome as well.[3,14–17]

The indoor environment in a confined space is a complex, dynamic combination of physical, chemical, and biological factors that may affect human health and prompt physical reactions. There is evidence that volatile organic compounds commonly found in office air can cause symptoms typical of the sick building syndrome.[18,19] Exposure to environmental tobacco smoke, which consists of various chemical substances and particulates, has also been related to these symptoms.[4,6,20] Studies in which people subjected to spaces with wall-to-wall carpets,[21] fleecy material,[10] or textile surface material[22] reported more symptoms than people in similar spaces without those materials have provided indirect evidence of the importance of biological particles. In addition, indoor air temperature[5,23] above 22°C and relative humidity[24] below 25% have also been associated with an excess of sick building syndrome symptoms in cross-sectional studies. A six-period crossover trial[25] among office workers was able to show that symptoms common in low relative humidity (20% to 25%) can be prevented by modest air humidification (raising relative humidity to 30% to 35%).

In addition to the quality of outdoor air and emissions from the indoor environment and occupants, indoor air quality is affected by type and performance of heating, ventilating, and air-conditioning technology. In mechanical ventilation and air-conditioning systems, recirculation of air is used to control temperature and air distribution and to conserve energy. In this type of ventilation system, a part of the exhaust air from the rooms (return air) is recirculated back to the supply airflow, which is a mixture of return air and outdoor air (Figure 1). Air recirculation can be quantified in terms of the proportion of return air in the total airflow. Proportions of recirculated air as high as 80% to 90% are common in North America whereas, in Finland, they are usually between 30% and 70%.

This paper was accepted August 10, 1993.

Editor's Note. See related editorial by Mendell and Fine (p 346) in this issue.

The rate of the total and outdoor air supply are other important parameters when studying the effects of air recirculation. It is evident when outdoor airflows are too low, indoor pollutants can accumulate in concentrations that can cause sick building syndrome symptoms. In 1987, a Nordic research meeting considered the use of air recirculation to be a "risk solution" and recommended against it in public buildings.[26] This recommendation was justified by the risk of spreading indoor air pollutants and by the prevailing poor technology and maintenance of systems involving recirculation.

We carried out a blinded, four-period crossover trial to test the hypothesis that the use of recirculated air in mechanically ventilated office buildings with sufficient intake of outdoor air (exceeding the regulatory recommendations) and without any unusual internal sources of indoor air pollution causes mucosal irritation, skin reactions, allergic reactions, and general symptoms (commonly known collectively as the sick building syndrome), as well as perceptions of unpleasant odor, stuffiness, or dustiness.

Methods

Buildings and Study Population

Two identical office buildings in Kilo, 15 km from the center of Helsinki, were selected as suitable for our study. Constructed in 1974, these buildings have eight stories and are 72 m long, 18 m wide, and 35 000 m^3 in volume. The structure of each is concrete, and the windows can be opened. Each building has a central mechanical ventilation system, hot water radiators for heating, and two identical air handling units, which are operated only during office hours, from 7 AM to 5 PM. The proportion of return air, ordinarily 30% to 40% during the heating season, is selected by adjusting the blades of the dampers.

From the source population—the 470 workers in the two buildings—all those who met the following eligibility criteria were targeted for recruitment to the study population: (1) experience, during the previous 12 months, of symptoms and/or perceptions of poor indoor air quality, which were attributed to the work environment generally or to the indoor air quality specifically; (2) work in an assigned room on the average of at least 3 days a week; (3) no anticipated absence from work during the study period owing to vacation, trip, or other reason; (4) no doctor-diagnosed asthma; and (5) no regular exposure to environmental tobacco smoke in the office. The resultant study population—the 75 persons who fulfilled these criteria—is described in Table 1.

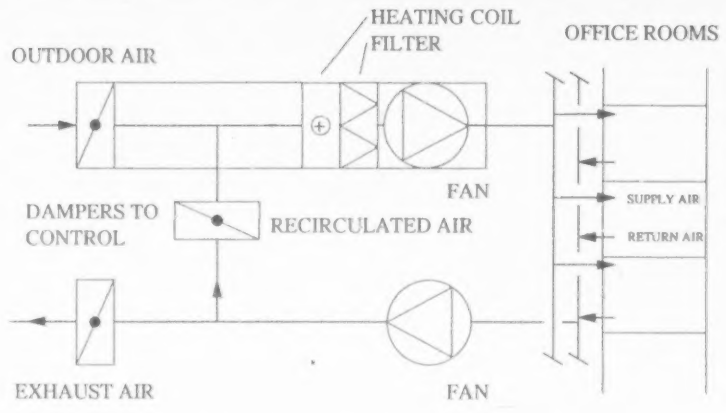

FIGURE 1—A schematic presentation of the air handling system used in the two buildings.

Recirculation

We tested our hypothesis in a blinded four-period crossover trial in November-December 1988; each period consisted of 1 workweek. For the week just before the experiment, both buildings were ventilated without recirculation, with a total airflow of 20 liters per second (L/s) per person. During the first experimental week, based on random selection, one building (building A) was operated with 70% recirculation while no recirculation was used in the other building (building B). The operation of the recirculation system was then switched during the weekend so that this procedure was reversed during the second week. A similar crossover procedure was carried out two more times. Thus, each participant experienced two periods of exposure to recirculated air (index periods, index phase) and two

periods of no exposure (reference periods, reference phase).

The total supply airflow was kept constant at 20 L/s per person through the experiment. The system was designed to provide outdoor air at the rate of at least 4 L/s per person (the recommended minimum rate in Nordic countries during the study). No air humidification was used in the buildings. The participants were told that ventilation would be adjusted during the study, but neither the objective nor the phase of the study was revealed. Thus, the trial was blinded.

Outcome Criteria

Apart from particular symptoms per se, four outcome scores were defined, based on theories regarding potential health effects of air recirculation, and the reporting of corresponding symptoms (i.e., the symptoms that appear in each outcome score based on the theory) was used in forming them. With a partial overlap of elements, these scores were as follows:

1. *Mucosal irritation score*, based on scores for dryness, itching, or irritation of eyes; nasal dryness; nasal congestion ("stuffy nose"); and pharyngeal irritation
2. *Skin reaction score*, based on scores for dryness, itching, or irritation of skin, and rash
3. *Allergic reaction score*, based on scores for dryness, itching, or irritation of eyes; nasal congestion; nasal excretion ("runny nose"); sneezing; and cough
4. *General symptom score*, based on scores for headache and lethargy

Scores for the perception of unpleasant odor, stuffiness, or dustiness were additional outcome criteria.

Data Collection

During the trial, participants were asked to fill out a diary each day after work recording whether and to what extent they had experienced any of the outcome symptoms (structured answers: no = 0, mild = 1, moderate = 2, severe = 3) and had perceived unpleasant odor, stuffiness, or dustiness (scale from none = 0 to pervasive = 5). A sensation of dryness and of temperature was also requested (scale: all too humid/cold = 1, too humid/cold = 2, acceptable = 3, too dry/warm = 4, all too dry/warm = 5). Extraneous determinants of the outcomes were also inquired about daily. These included symptoms of the common cold (no symptoms = 0, cold and/or sore throat = 1, cold and/or sore throat and fever = 2); sensations of tobacco smoke in a nonsmoking room (scale from none = 0 to extensive odor = 3); the number of cigarettes smoked in the office by participant, roommates, and visitors; the time the window was open, and the reason for opening the window.

Air Measurements

Airflow, temperature, and relative humidity were measured on Tuesdays and Thursdays in all rooms during each period. Airflow was measured in the exhaust air register of each office using a calibrated Wallac anemometer with a relative error of less than 15%. Air temperature and relative humidity were measured with VAISALA HMI-31 capacitive sensors whose accuracy is ±0.3°C for temperature and ±2% for relative humidity. Supply airflow and proportion of return air were measured in the beginning and end of each period using the tracer gas method.

Data Reduction

The detailed data consisted of daily ratings (maximum 20 days) of the component symptoms, and perceptions of and structured answers to the questions on the extraneous factors. The outcome scores were calculated by adding the component symptom ratings and dividing the sum by the number of symptoms. For each participant, the means of the daily outcome scores and the ratings for the component symptoms and the perception of indoor air quality were calculated for both index and reference phases and the difference between these. Days in which less than 2 hours were spent in the office building were excluded. The subjects were also classified, for each item, according to those who reported more, the same number, or fewer symptoms/perceptions of poor indoor air quality during the index phase.

Statistical Methods

The primary hypothesis—that the use of recirculated air causes symptoms and perception of poor indoor air quality—was tested by comparing the means of the outcome criteria in the index, or recirculation, phase with those of the reference phase. In the primary analysis, differences between these means were assessed for statistical significance by using the paired t test, and the 95% confidence interval was calculated for the estimate.[27] The role of period effect was assessed in a general linear model using the SAS® computer package (procedure *proc glm*), as described by Senn.[27] The probability ratio between experiencing more and fewer symptoms/perceptions during the index phase as compared with the reference phase was also estimated. This was done by dividing the number of participants with more symptoms/perceptions during the index phase by the number of participants with fewer symptoms. The statistical significance was evaluated by means of McNemar's test, and the 95% confidence interval for the probability ratio was calculated by Miettinen's test-based method.[28] The primary analyses were carried out blinded to the two phases. The analyses were carried out first for the total study population and then for the subjects who had in the baseline questionnaire indicated having the corresponding symptom/perception during the previous 12 months.

Results

Experimental Conditions

The proportion of return air during the study period was achieved reasonably well according to the study design. It ranged from 69% to 71% during the index periods and from 1% to 6% during the reference periods (the result of leaky dampers). The total supply airflow in the 67 study rooms was somewhat lower during the index phase (mean = 20 L/s per person, range = 6.3–95.6, SD = 13.2) than during the reference phase (mean = 23 L/s per person, range = 6.0–77.2, SD = 12.8). Temperature was somewhat higher during the index phase (23.4°C, range = 21.9–24.8, SD = 0.6) than during the reference phase (23.1°C, range = 21.8–24.4, SD = 0.6). The relative humidity ranged from 23% to 28% during the first 3 weeks and from 14% to 20% during the fourth week. The mean relative humidity was 1% greater during the phase with air recirculation than during the phase without.

Participation

All 75 members of the study population returned their symptom diaries. Focus on the subjects who were in the office for at least 2 hours on at least 1 day in each of the two phases led to the deletion of three subjects.

Outcomes

The means of the symptom scores and the component symptom ratings during the index and reference phases are given in Table 2, together with the differences between them and their 95% confidence intervals based on intraindividual differences. The mean differences in the symptom scores did not differ from zero more than could be expected by chance. Of the single symptoms, the mean rating for sneezing was significantly lower during the index phase (0.24) than during the reference phase (0.33). The means of the outcome scores/ratings were higher in those who had corresponding symptoms during the previous 12 months, but there were no significant differences between the two phases.

Ratings of air for perceived poor quality were not higher during the index phase than during the reference phase (Table 2). On the contrary, the mean of unpleasant odor ratings was significantly lower during the index phase (0.19 vs 0.35).

The numbers of participants with more, fewer, and the same number of different symptoms and perceptions during the index phase as compared with the reference phase and the empirical probability ratio for having more symptoms/perceptions are given in Table 3. The number of subjects with more problems during the use of recirculated air did not differ significantly from the number of those with fewer problems, either in the total study population (Table 3) or in those with corresponding symptoms/perceptions during the previous 12 months.

Extraneous Factors

There were slightly more subjects with symptoms of the common cold during the reference period than during the index period (20 vs 23). The participants spent, on average, 8 minutes per day less in the office during the index phase than during the reference phase. Similarly, there were slight differences in smoking in the office (personal smoking per day: index = 0.52 cigarettes, reference = 0.60 cigarettes; other smoking per day: index = 0.22 cigarettes, reference = 0.24 cigarettes), perception of tobacco odor (index = 0.29, reference = 0.25), and opening of the windows (index = 11 minutes per day, reference = 13 minutes per day) during the two periods.

TABLE 2—Means of Symptom Scores and Ratings of Component Symptoms during Index and Reference Phases and Their Differences

Outcome	Index	Reference	Intraindividual Differences	
			Point Estimate	95% CI
Mucosal irritation score	0.42	0.44	−0.015	−0.066, +0.036
Eye symptoms[a]	0.22	0.24	−0.014	−0.067, +0.039

Discussion

The possibility that the use of recirculated air causes adverse health effects or discomfort became a public concern at a time when there was no empirical evidence to support or refute it. However, there were two theoretical models according to which the use of recirculated air could cause adverse effects. Berglund and Lindvall[29] suggested that the human sensory system uses a pattern recognition mechanism in the sensation of indoor air with complex environmental adaptation to the inhaled air. Use of a high proportion of recirculated air can lead to extreme homogenization of air, causing sensory confusion and strain on the system when it is trying to interpret the signals. According to the hypothesis, "sensory symptoms tied to 'sick buildings' of the irritant type"[25(p157)] could be related to the homogenization of air. In another theoretical model, which was based on the physical property of recirculation, indoor air pollutants from different point sources are circulated, causing low-level exposure to a mixture of chemical and biological pollutants, which can in turn cause mucosal irritation, skin and allergic reactions, and general symptoms. Thus, the use of air recirculation was hypothesized to produce conditions with adverse health effects; the methods to measure these conditions, however, are poor even with the best of technology.

The sick building syndrome has not been defined properly as a scientific concept, and so far no unifying mechanism has been postulated. We attempted to define the outcome criteria conceptually as biological reactions, mucosal irritation, and allergic reactions. We described the reactions operationally by the chosen symptom scores. The skin reaction score and general symptom score were also used as outcome criteria without any hypothesized mechanism; this was justified because these symptoms have also been attributed to the sick building syndrome.[1-4,8,13-15] General symptoms have also been addressed in earlier studies[8-10,29] without a hypothesized mechanism. The choice of symptoms related to a given mechanism is difficult, and there may be disagreement about the correctness of the choices. In our results, we also showed the occurrence of each component symptom to enable critical readers to evaluate the choice of symptoms or to choose their own combination.

The study population of 75 office workers was recruited from a source population of 470 office workers because they indicated having symptoms or perceived poor air quality related to the work environment at baseline. These subjects thus represented the most sensitive workers, those in whom the effect was most likely to be manifest. Further analyses were carried out focusing on those who had indicated having the corresponding symptom or perception related to the work environment during the previous 12 months when 30% to 40% of recirculated air had been used.

The experimental study design ensured the study's validity because intraindividual comparison of symptoms between different environmental conditions eliminated the potential confounding by personal characteristics. The exact purpose and the phase of the study were not revealed to the study subjects, and thus the information from the index and reference periods was comparable. The length of the periods, 1 week, was deemed adequate for postulated short-term effects. The weekends were considered, a priori, as sufficient washout periods to prevent the effect of exposure in one period to be carried over into a subsequent period. The period effect was found to be negligible in assessing the effect of air recirculation.

The amount of outdoor airflow is directly related to the capability of removing indoor air pollution from a given space. Keeping the total supply airflow constant and varying the proportion of recirculated air, as we did in our study, corresponds to the real-life situation. Our design purpose was to keep room temperature, relative humidity, and total supply airflow similar during the index and reference periods. However, the use of air recirculation had some minor effects on other indoor air factors: the room temperature increased, on average, by 0.4°C; the relative humidity increased by 1%; and the supply air intake rate decreased by 3 L/s per person. Room temperature above 22°C has been shown to increase the symptoms associated with the sick building syndrome.[5] According to an earlier study in Finland,[24,25] an increase in relative humidity in this range is likely to decrease the occurrence of eye and skin symptoms. In the marginal range, a decrease of supply airflow could increase indoor air pollution and thus the symptoms, but during the study the mean supply airflow was 21 L/s per person (minimum was 6 L/s per person) and thus the average decrease was less than 15%. During the index period, the mean outdoor airflow was 6 L/s per person (minimum was 2 L/s per person). In all, the differences in temperature, relative humidity, and supply airflow between the index and reference periods were small and thus were not likely to affect the results.

Uneven distribution of extraneous factors could have affected the validity of the study. To take this potential confounding into account, most important extraneous factors were recorded during the study period. Symptoms of the common cold were slightly more common during the reference phase, which may explain the observed excess in sneezing, nasal excretion, and cough. In all, the differences in the extraneous factors were very small and thus were unlikely to detract from the validity of the study.

The use of 70% recirculated air in the context of sufficient intake of outdoor air appeared not to increase mucosal irritation, skin or allergic reactions, or general symptoms, nor to increase the reporting of poor air quality. Thus, the findings of this study detract from the theory that change in the physical character of air due to recirculation (homogenization) causes the symptoms of the sick building syndrome.[29] Similarly, the use of a high mechanical ventilation rate in another experimental study,[4,6] which was also suggested as a cause of the homogenization of indoor air,[29] appeared not to cause these symptoms.

The present study can also be interpreted as a comparison of the effect of two levels of outdoor air supply (6 vs 20 L/s per person) on the occurrence of sick building syndrome symptoms and perceptions, if the hypothesis of the homogenizing effect of air recirculation, per se, is ignored. The role of air change as a determinant of such symptoms has been assessed earlier at least in five experimental studies.[4,6,30-33] It is evident that too small an air change allows indoor air pollutants to accumulate and that low airflows can thus be indirect determinants of both symptoms and other health problems. In a controlled trial of 46 Canadian office workers in 1980, Sterling and Sterling[30] varied the proportion of outdoor air between 87% (13% return air) and 25% (75% return air) with a constant total airflow, and observed a decrease in the occurrence of

eye symptoms related to an increase of outdoor air intake. In a controlled trial of 940 Finnish office workers carried out in 1985, a temporary reduction of originally high airflows resulted in an increase in the symptoms of the sick building syndrome[4,6] in outdoor airflows below 7.5 L/s per person. Nagda and colleagues[31] carried out an uncontrolled trial in the summer of 1989 and the winter of 1990, in which they compared the occurrence of symptoms in two levels of outdoor air supply (9 and 16 L/s per person) and reported more building-related symptoms during the low outdoor air supply than during the high outdoor air supply. In two experimental studies, no association was observed between the different levels of outdoor air supply.[32,33] Wyon[32] assessed experimentally the relation between the level of airflows and the occurrence of sick building syndrome symptoms in Malmö General Hospital staff: neither a 30% decrease nor 40% increase had an effect on the occurrence of symptoms. Menzies and colleagues[33] carried out a six-period crossover trial among 1546 Canadian office workers in 1990 "to test the hypothesis that symptoms of sick building syndrome could be reduced in mechanically ventilated office buildings by increasing supply air from 20 to 50 ft^3 per minute per person"[30(p821)] (9 and 23 L/s per person). The results were in line with the present study: the occurrence of ocular, mucosal, and general symptoms was similar with the different levels of outdoor air supply (the actual airflows were 14 and 30 L/s per person). The main difference between the two studies is that, in the Canadian study, the proportion of return air was high (68% and 93%) in both levels of outdoor air supply, whereas in the present study, 70% return air was contrasted with no return air. The role of air recirculation and outdoor air supply as determinants of the symptoms cannot be fully separated in the studies where the compared conditions include a high proportion of return air.

Sufficient air change depends essentially on human activities, sources of air pollution, net emission, and the presence of alternative exhaust routes such as operable windows and diffusion through the walls. Thus, the studies that were carried out in a small number of buildings should be used cautiously when considering the standards for minimum air change. The inconsistency in the results of different studies as to the relation between air change and the symptoms of the sick building syndrome is probably explained by differences in the indoor environment of the buildings.

Our results provided evidence that 70% recirculated air, when accompanied by an adequate intake of outdoor air, can be used without causing adverse effects. Another approach is needed to evaluate whether a ventilation system using air recirculation can be considered a risk solution in existing buildings—that is, whether the adverse health effects occur more often in buildings with such a ventilation system compared with buildings without the use of air recirculation. □

Nitrogen Dioxide Exposures inside Ice Skating Rinks

Michael Brauer, ScD, and John D. Spengler, PhD, MS

ABSTRACT

Objectives. The common operation of fuel-powered resurfacing equipment in enclosed ice skating rinks has the potential for producing high concentrations of carbon monoxide and nitrogen dioxide. Exposures to these gaseous combustion products may adversely affect the health of those inside the rink. Little information is available on pollutant concentrations under normal operating conditions.

Methods. One-week average nitrogen dioxide concentrations in 70 northeastern US rinks were measured with passive samplers during normal winter season conditions.

Results. The median nitrogen dioxide level inside rinks was 180 ppb, more than 10 times higher than the median outdoor concentration. One-week average nitrogen dioxide concentrations above 1000 ppb were measured in 10% of the rinks.

Conclusions. Considering that short-term peak concentrations were likely to have reached two to five times the measured 1-week averages, our results suggest that nitrogen dioxide levels were well above short-term air quality guidelines and constitute a public health concern of considerable magnitude. (*Am J Public Health.* 1994;84:429–433)

Introduction

In skating rinks, the operation of gasoline- or propane-powered equipment to clean and resurface the ice can lead to elevated concentrations of combustion products. Reports indicate that high concentrations of carbon monoxide in ice rinks occasionally lead to toxicity.[1–6] Recently, acute respiratory illness due to nitrogen dioxide exposure has also been reported at indoor ice rinks.[7–11]

Acute exposure to nitrogen dioxide concentrations above 5 to 10 parts per million (ppm) may produce severe cough, hemoptysis, chest pain, and pulmonary edema.[12–14] The effects of exposure to lower levels (0.1 to 1 ppm), such as those encountered in homes using gas stoves or kerosene heaters, are more debatable. Controlled exposures of healthy (nonasthmatic) individuals to nitrogen dioxide concentrations above 1000 parts per billion (ppb) (exposure for 1 hour or longer) indicate increased airway responsiveness,[15–17] whereas exposures to lower levels have not produced any effects. On the other hand, controlled chamber studies with asthmatics suggest that small changes occur in spirometric measures and airway responsiveness for short-duration exposures to 100 to 500 ppb nitrogen dioxide.[15,18,19] However, other studies have shown no respiratory effects in asthmatics following exposures to higher levels.[20,21] Consequently, asthmatics are considered to be especially susceptible to respiratory effects of nitrogen dioxide exposure.

Because controlled chamber studies have involved mostly adult subjects, epidemiological studies may have more relevance to the ice skating population since they investigated children. Neas and colleagues report an odds ratio of 1.45 for lower respiratory symptoms in children for an increase in the annual average nitrogen dioxide concentration of 15 ppb.[22] A recent meta-analysis of 11 epidemiological studies yielded similar results, suggesting a 20% increase in the odds of a lower respiratory infection for children with a prolonged increase in exposure to 16 ppb nitrogen dioxide.[23]

Although occurrences are infrequent and are typically associated with resurfacer malfunction, which produces peak nitrogen dioxide concentrations of 1000 to 3000 ppb, reports of acute nitrogen dioxide poisoning in ice rinks demonstrate that an acute exposure in this setting can lead to respiratory illness. In contrast, we sought to examine the potential public health impact of repeated exposures to nitrogen dioxide by investigating the range of concentrations encountered in skating rinks under normal operating conditions. We hypothesized that ice rinks presented the major nitrogen dioxide exposure of users and that, based on comparisons with epidemiological studies of indoor exposures, levels of nitrogen dioxide encountered in ice rinks warrant concern.

Methods

A mail-in survey was conducted in spring 1990. One hundred seven rinks

TABLE 1—Measured Nitrogen Dioxide Concentrations in Enclosed Rinks

Location of Sampler	No.	Geometric Mean, ppb	Geometric SD	Range, ppb
Outdoors	54	17.6	2.4	0.44–193
Resurfacer	57	128.0	3.6	3.11–1428
Bench	57	169.0	4.0	3.11–2140
Rink sample 2	53	168.0	4.0	1.76–2470

were contacted and asked to deploy passive nitrogen dioxide sampling devices and to complete a questionnaire. Sampling tubes, instructions, and questionnaires were mailed to all participants, and follow-up contact was made by phone. Strict criteria on sample placement and handling were described: all samplers were to be deployed for the same 7-day duration at all rinks, with at least one sampler placed immediately outside the rink but away from parking lots and major traffic areas (outdoors), one sampler placed on the main resurfacer (resurfacer), one sampler placed at the scorekeeper's bench as close to breathing height as possible (bench), and one sampler placed at the opposite side of the rink from the scorekeeper's table (rink sample 2). Additionally, each sampling packet contained either a field blank or a duplicate sampler to be placed at one of the four designated sites along with the primary sampler. Nitrogen dioxide concentrations were measured with Palmes tubes diffusive samplers, which provide an integrated average of the nitrogen dioxide concentration over a defined sampling interval.[24-26] Following the sampling period, participants returned the sampling tubes to our laboratory for analysis.

Along with the sampling tubes, participants returned a completed questionnaire describing the use of the rink and resurfacing equipment, the physical characteristics of the rink, and the building's ventilation. Questions regarding rink age and seating capacity were asked for their potential use as surrogate data for building air tightness and volume, respectively. Except where indicated, the scorekeeper's bench sample was used to measure the indoor concentration of the rink. Additionally, open-air rinks were excluded from the analysis except where specifically stated. Relationships between nitrogen dioxide concentrations and rink variables obtained from questionnaires were examined by viewing scatter plots of concentration data, log-transformed concentration data, and single-factor analysis of variance of log-transformed concentration data.

Results

Valid samples and questionnaires were obtained from 70 of the 107 (65%) rinks contacted for the survey, a response rate that is in good agreement with other mail-in air pollution surveys.[27,28] Literature reports[8] and discussions with industry representatives indicate that there are more than 2000 operating ice rinks in North America. While the 70 rinks included in our survey were not intended to constitute a random representative sample, they do represent a significant proportion of operating rinks in New England.

Summary statistics of nitrogen dioxide concentrations are presented in Table 1. Samples of outdoor concentrations were substantially lower than any of the other samples for all rinks but one, with the median indoor concentration amounting to approximately 10 times the median outdoor level. Indoor concentrations from both samples in each rink were similar, indiating that nitrogen dioxide concentrations were quite homogeneous near the ice surface. Rink samples were also higher than the sample collected on the resurfacer, owing to the storage of the resurfacer either outdoors or in a garage when not in use. The resurfacer concentrations of nitrogen dioxide therefore should not be interpreted as a measure of resurfacer operator exposure.

Significant differences ($P < .05$) in nitrogen dioxide concentrations were observed between enclosed (geometric mean = 169.5 ppb; geometric standard deviation [SD] = 4.0; n = 58) and open rinks (geometric mean = 16.2 ppb; geometric SD = 1.57; n = 9), with greater differences observed if the enclosed rink did not have a ventilation system. Nitrogen dioxide concentrations in enclosed rinks without ventilation systems (geometric mean = 329.7 ppb; geometric SD = 3.7; n = 7) were higher than those in rinks with ventilation systems (geometric mean = 154.7 ppb; geometric SD = 4.0; n = 51), although the difference was not significant. The presence of a ventilation system in a rink does not necessarily mean that the system was in operation or was being operated at full capacity.

Although trends were evident, no other statistically significant differences in nitrogen dioxide concentrations were observed. Higher nitrogen dioxide concentrations were measured in rinks with propane-fueled resurfacers (geometric mean = 221.1 ppb; geometric SD = 3.3; n = 27) than in rinks using gasoline-powered resurfacers (geometric mean = 134.0 ppb; geometric SD = 4.6; n = 31); such a finding was expected because of the lower combustion temperature of propane relative to gasoline and the consequent increase in nitrogen dioxide emissions. None of the rinks tested used diesel- or electric-powered resurfacers, although these are commercially available. The presence of catalytic converters was distributed evenly between the two fuel types of resurfacers; rinks with a resurfacer containing a catalytic converter had higher nitrogen dioxide levels (geometric mean = 214.0 ppb; geometric SD = 3.3; n = 25) than rinks with a resurfacer that lacked a catalytic converter (geometric mean = 140.0 ppb; geometric SD = 4.3; n = 31). This result is explained by the oxidative properties of the catalyst, which is designed to convert carbon monoxide to carbon dioxide. Ninety-two percent of rinks used a resurfacer with a four-cylinder engine; 7% used an eight-cylinder model, and one rink used a six-cylinder model.

Rink size, as measured by seating capacity, was not a significant determinant of nitrogen dioxide concentration. This may be owing to inadequate air mixing in rinks, such that the effective volume of elevated nitrogen dioxide is smaller than the total rink volume. This is possible given the temperature stratification within enclosed rinks,[1] where cool air near the ice surface prevents effective mixing of the combustion emissions with the warmer air above. Thus, seating capacity may be a poor surrogate for rink volume. The number of resurfacings per day also was not a significant predictor of nitrogen dioxide concentration, although this was probably owing to the low sample sizes of rinks with fewer than 10 or more than 13 resurfacings per day.

Table 2 summarizes the rink characteristics.

Discussion

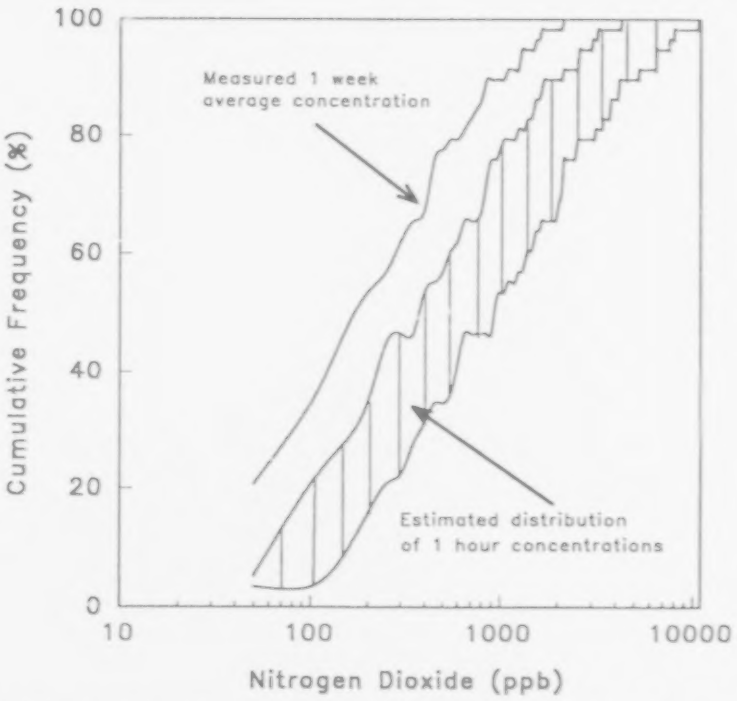
To estimate the importance of nitrogen dioxide exposures in ice rinks, we compared our measurements with those from other environments. Typical ambient nitrogen dioxide concentrations in urban areas are below 50 ppb, with infrequent hourly values above 200 ppb. Indoor concentrations are often much higher than ambient values, particularly in homes with unvented gas appliances. Since more than 40% of US homes contain gas appliances, the problem of elevated indoor nitrogen dioxide is more widespread. Extensive (2-week average) measurements in Boston homes with gas stoves[29] report median concentrations of 20 to 40 ppb, depending on the season of the measurement and the location in the home where the measurement was collected. Ninety-ninth-percentile values of approximately 100 ppb were recorded for kitchen measurements in all seasons except summer. During cooking, peak nitrogen dioxide concentrations of 450 ppb (1-hour average) are sustained for 1 to 2 hours.[30] This scenario of short-duration intermittent exposures is similar to the 1- to 3-hour exposures experienced by spectators and skaters in ice rinks; rink employees as well as coaches and figure skaters are likely to be exposed for longer periods (4 to 8 hours). Skaters are probably the most susceptible to health effects of air pollutants in an ice skating rink since ventilation rates while skating are expected to exceed normal resting breathing rates by three to five times.[4]

The detailed study by Lee and colleagues[31] adds insight into the peak nitrogen dioxide concentrations produced inside ice rinks. If the temporal distribution of nitrogen dioxide and carbon monoxide concentrations in ice rinks are similar, we estimate that 1-hour nitrogen dioxide concentrations would be two to five times the measured 1-week average (Figure 1). Assuming that the parameters assessed in our survey are typical of the more than 2000 ice rinks in operation in the United States and Canada, a rink is staffed by employees for 14 hours and visited by 300 people (for 1 to 2 hours) daily (Table 2). Therefore, 500 000 or more individuals per day may be exposed to concentrations of nitrogen dioxide that are well above the highest measured ambient and indoor levels. Repeated exposures are common, since high school and college hockey teams practice daily from September to April and recreational players skate once or twice weekly. The high levels of nitrogen dioxide encountered in ice skating rinks present an extreme exposure not likely to be encountered in other indoor, ambient, or occupational settings.

TABLE 2—Ice Rink and Resurfacer Use Characteristics, All Rinks

	Mean	SD	Range
Seating capacity	1228	1461	0–7800
Rink age, y	20	13	1–86
Rink use, h/d	14	3.4	7–20
Users per day	352	218	75–1000
Resurfacer use, min/wk	740	227	168–1260
Tuneups per year	6	8	1–52
Edger use, min/wk	104	420	5–420

Note. Numbers listed are for typical weekdays. In many rinks, weekend user numbers increase to two to five times the weekday numbers.



Note. Distribution of 1-hour concentrations is based on peak levels, which are two to five times higher than the measured 1-week average.

FIGURE 1—Cumulative frequency distribution of measured (1 week average) and estimated short-term peak (1 hour average) nitrogen dioxide concentrations in enclosed ice skating rinks.

Measurements of carbon monoxide and nitrogen dioxide collected after serious poisoning incidents indicate that levels probably exceeded even ceiling limits for occupational conditions.[32] From a regulatory standpoint, then, it is most important to eliminate incidents through corrective action and to set air quality standards for normal operating conditions at levels well below those that lead

to measurable acute effects. Minnesota has enacted air quality standards for ice arenas[33,34] stipulating that immediate corrective action must be taken when carbon monoxide exceeds 34 ppm or nitrogen dioxide exceeds 0.5 ppm (1-hour average) and requiring rinks to be evacuated when carbon monoxide exceeds 125 ppm or nitrogen dioxide exceeds 2 ppm. This standard protects against accidents where immediately dangerous levels of pollutants are present, but it is insufficient to provide a margin of safety to protect susceptible subgroups, such as asthmatics or children.

Although policy for indoor air quality has not yet been developed by the US government, short-term guidelines (1-hour average) of 200 ppb and 250 ppb nitrogen dioxide have been published for residential indoor air by the World Health Organization (WHO)[35] and the Department of National Health and Welfare Canada,[36] respectively. These guidelines are designed to protect sensitive members of the population (such as asthmatics) with an adequate margin of safety. Although these guidelines are more pertinent to ice rinks than are ambient air standards, they were developed primarily for residential environments and therefore have only limited applicability for indoor ice arenas. Moreover, because skaters are often young children, occupational standards based on a healthy adult worker are not appropriate.

Figure 1 indicates that at least 60% of the rinks included in this survey would exceed the 1-hour WHO limit of 200 ppb or the Canadian guideline of 250 ppb. In fact, it may be premature to emphasize an air quality standard for ice rinks when so many rinks are likely to be out of compliance. Instead, efforts should be directed toward education, design, and operational changes in order to mitigate the impact of resurfacers on air quality.

Strategies to maintain 1-hour nitrogen dioxide and carbon monoxide concentrations below 250 ppb and 35 ppm, respectively, are recommended. For example, warming the resurfacer engine with the exhaust vented outside will reduce indoor concentrations of carbon monoxide; however, this strategy is not effective for reducing nitrogen dioxide emissions. For many enclosed rinks, preventing short-term nitrogen dioxide levels from exceeding 250 ppb (1-hour average) will require increased ventilation and/or reduced use of resurfacing equipment. During a typical 11-minute resurfacing operation using a well-maintained resurfacer, approximately 5 L of nitrogen dioxide are released (Appendix). This volume of nitrogen dioxide would have to be diluted with 20 000 m^3 of clean air to achieve a concentration of 250 ppb. With hourly resurfacings, a typical rink building of 22 000-m^3 volume would require nearly one air exchange per hour or 13 000 cu ft of ventilation air per minute. Furthermore, mechanical ventilation systems must be designed so that the cooler air over the ice surface, which contains the highest concentrations of nitrogen dioxide, mixes adequately.

Depending on the location of the rink, additional heating of the ventilation air may be required. Across the region where most of the ice skating rinks are found (throughout Canada, the midwestern United States, and New England), heating degree-days range from 5000 to 10 000. Since indoor temperatures for ice rinks tend to be in the low 40s (°F), we used 5000 degree-days to compute the additional energy required for a rink building to achieve one air exchange per hour. For example, a gas-fueled heater with a heat exchanger at a fuel price of $0.005/cu ft would cost $6000 to $8000 annually to operate. For the approximately 50% of rinks that operate for the entire year, providing chilled dehumidified air in the summer could more than double these energy costs. Since our survey found that 10% of the enclosed rinks do not even have a ventilation system, certain rinks would also need to incur large capital costs to achieve desirable air quality.

An alternative approach is to replace existing gasoline- or propane-fueled resurfacers with electrically powered units. Since resurfacers typically have operating lifetimes of 20 to 30 years and cost $60 000 to $70 000, replacement of existing resurfacers is equivalent to an annual cost of approximately $3000.

This paper, along with reports on outbreaks of illness, points to the potential seriousness of exposures to air pollutants in ice rinks. Public health officials should recognize that inadequate ventilation and poor maintenance of the resurfacer can result in nitrogen dioxide and carbon monoxide levels that are injurious to normal healthy individuals. However, even when equipment is properly maintained, inadequate ventilation will result in nitrogen dioxide levels that can evoke airway responses in asthmatics. Health agencies are encouraged to enact requirements to prevent potentially deleterious exposures in enclosed ice skating arenas. □

APPENDIX—Estimation of Nitrogen Dioxide Emission Rate

The average carbon monoxide emission rate as measured by Lee et al.[31] was 9 L min^{-1}. During measurements, there were 14 resurfacings lasting 10 minutes each; these resulted in a total emission of 1260 L of carbon monoxide, emitted into a rink building with a volume of 20 000 m^3, with an air exchange rate of 0.2 hr^{-1}. The resulting concentration of carbon monoxide was 13 ppm.

During this same period, 700 ppb of nitrogen dioxide were measured. Assuming that carbon monoxide and nitrogen dioxide have the same emission and concentration profile, the measured concentration of 700 ppb nitrogen dioxide corresponds to a total emission volume of 68 L nitrogen dioxide and an emission rate of approximately 0.5 L min^{-1} nitrogen dioxide. This estimated emission rate is likely to be an underestimate of the true nitrogen dioxide emission rate since this calculation assumes that carbon monoxide and nitrogen dioxide have identical decay rates when, in fact, nitrogen dioxide is likely to decay significantly faster than carbon monoxide.

The Respiratory Health Impact of a Large Urban Fire

ABSTRACT

Objectives. In July 1988, a fire destroyed a huge supermarket warehouse in Richmond, Calif, sending smoke into residential neighborhoods for nearly a week. There was no organized public health response. To evaluate the respiratory health impact on the general population, a survey of emergency room visits and hospital admissions to the two acute-care hospitals serving the population downwind was conducted.

Methods. Medical records of 489 patients meeting specified diagnostic criteria during the week of the fire and several reference periods were abstracted. Ratios of proportions for respiratory diagnoses (i.e., emergency room visits for a given diagnosis/total emergency room visits) were calculated, comparing the fire week with the reference periods, and 1988 mortality data for the area were reviewed.

Results. Ratios of proportions for emergency room visits for asthma and all lower respiratory conditions increased significantly during the fire. Respiratory-related hospitalizations also increased. However, there was no observable increase in respiratory mortality.

Conclusions. This fire was found to have had a moderate impact on the respiratory health of local residents. Public health intervention is indicated to prevent respiratory morbidity when extended exposure to structural fire smoke is predictable. (*Am J Public Health.* 1994;84: 434–438)

Michael Lipsett, MD, JD, Kirsten Waller, MD, MPH, Dennis Shusterman, MD, MPH, Susan Thollaug, RN, MPH, and Wendel Brunner, MD, PhD

Introduction

In July 1988, a fire destroyed a 580 000-sq ft supermarket distribution warehouse in Richmond, Calif. The fire began at 10:00 PM on July 11, emitting huge quantities of smoke through July 16, although it was not completely extinguished until July 19. During this time, smoke drifted north and northeast intermittently into Richmond and San Pablo, cities with a combined population of about 104 000.[1,2] Hundreds of area residents telephoned or visited hospitals and municipal offices complaining about the smoke.[3] Initially, local government agencies believed that this was a typical structural fire, and no official warnings were issued nor were other protective public health measures undertaken.

The public health impact of general population exposures to purely structural fire smoke has not been documented in the published literature. Exposure to smoke from forest fires or from a mixed wildland-suburban fire, however, has recently been reported to result in significant increases in emergency room visits for respiratory conditions.[4,5] Smoke contains various respiratory irritants, including aldehydes, particles, acid aerosols, and other compounds. Analyses of air pollution in urban areas consistently show associations between ambient particle concentrations and a variety of adverse respiratory outcomes (although the composition of smoke is undoubtedly different from routine particle sources).[6–10] Several smoke constituents, in addition, have been demonstrated to provoke bronchoconstriction.[11–13] Exposure to smoke causes acute decrements in pulmonary function and increases in airway reactivity among firefighters and fire victims.[14–16]

The purpose of this study was to estimate any excess respiratory-related hospital use associated with a major urban fire. We surveyed respiratory-related emergency room visits and hospital admissions during the fire period and two reference periods to examine epidemiologically the acute morbidity associated with the Richmond conflagration. We also compared weekly respiratory-related mortality totals for Richmond and San Pablo during and after the fire with weekly totals during the rest of 1988.

Methods

Two acute-care hospitals serving the majority of the population in the area downwind of the fire agreed to participate in this survey. One such hospital is a 42-bed facility (about 36 000 emergency room visits annually) belonging to a health maintenance organization that served 65 000 members at that time; the other is a 246-bed private hospital

Michael Lipsett and Dennis Shusterman are with the California Office of Environmental Health Hazard Assessment, Berkeley. At the time of the study, Kirsten Waller was with the Centers for Disease Control's Division of Field Epidemiology, Atlanta, Ga.; she is currently with the California Department of Health Services, Berkeley. Susan Thollaug is with the Department of Social and Administrative Health Sciences at the University of California's School of Public Health, Berkeley. Wendel Brunner is with the Public Health Division of Contra Costa County's Department of Health Services, Martinez, Calif.

This paper was accepted September 30, 1993.

(about 25 000 emergency room visits annually).

The time periods selected for the survey included the fire period (the week of July 12 through 18, 1988), the week following the fire (July 19 through 25, 1988), and two reference weeks (July 8 through 14, 1986 and July 5 through 11, 1988), which were used to control for seasonal and annual trends in emergency room visits and admissions. (We were unable to use a week in 1987 because of a missing emergency room logbook.) All four periods began on a Tuesday to minimize day-of-the-week variability.

Emergency room logbooks and hospital admission listings were reviewed to identify patients who had presented with respiratory complaints or eye irritation, and to calculate total hospital admissions and emergency room visits. The medical records of patients with respiratory-related complaints were then abstracted for age, sex, date and time of emergency room visit or admission, chief complaint, and physician diagnoses. Multiple visits by the same individual were counted as separate visits.

For each emergency room visit or admission, one of the study abstractors assigned an *International Classification of Diseases*, 9th ed. (ICD-9) code to the principal physician diagnosis.[17] The diagnostic categories included the following: nasopharyngitis, sinusitis, pharyngitis, tonsillitis, laryngitis, tracheitis, upper respiratory infection (unspecified), allergic rhinitis, and upper respiratory hypersensitivity reaction (defined as upper respiratory conditions, ICD-9 codes 460–465 and 477); acute bronchitis and bronchiolitis, pneumonia, chronic obstructive pulmonary disease (including chronic bronchitis and emphysema), and asthma (defined as lower respiratory conditions, ICD–9 codes 466, 480–486, 490–492, 496, and 493); exposure to smoke and fumes from a conflagration (ICD–9 codes E891.9 and E891.2); and conjunctivitis (ICD–9 code 372). If the physician's primary diagnosis was incompatible with any of the above ICD categories, the chart was not abstracted. The diagnosis of viral syndrome was coded to one of the appropriate upper or lower respiratory ICD-9 codes, depending on the symptoms and physical findings reported; if the symptoms or findings were not referable to the respiratory tract, the chart was not abstracted. To compare the fire period with the reference periods, patients with an isolated diagnosis of smoke inhalation but with physical findings consistent with another diagnosis were coded to the latter. All emergency room visits and hospital admissions that were not coded to one of these ICD categories were defined as nonrespiratory.

We also evaluated patient charts for evidence of physical findings corroborating the physician diagnoses. We hypothesized that (owing to anxiety, legal concerns, and so forth) people may have been more likely to present with respiratory complaints but without physical findings during the fire period. This might have led to an overestimation of the respiratory effect associated with the fire. To control for this possible bias, we coded each emergency room visit or hospital admission in all time periods as "eligible" (with corroborating physical findings) or "ineligible" (without corroborating physical findings). A diagnosis of bronchitis was always coded as eligible since this diagnosis is often based on history alone. Patients given a diagnosis of smoke inhalation without any abnormal findings on physical, laboratory, or radiological exam were coded as ineligible. Although the abstractors were not blinded to the time period of the visit or admission, each case for which the determination of diagnosis or eligibility code was not straightforward was discussed in group meetings. In these discussions, only the abstractor was aware of when each visit or admission occurred, and codes were assigned based on consensus reached without regard to the time period.

Data entry and analysis were performed using Epi Info.[18] Epidemic curves were constructed by plotting daily numbers of respiratory- and nonrespiratory-related emergency room visits during the prefire, fire, and postfire periods. Ratios of proportions (RPs) of specific diagnostic categories, comparing the fire week to the two prefire reference weeks, were calculated using the following formula for each diagnostic category:

$$RP = \frac{\text{Number of visits for the diagnosis/total visits during the fire period}}{\text{Number of visits for the diagnosis/total visits during the reference periods}}$$

Chi-square tests were performed to test the homogeneity of the proportions of visits for respiratory and nonrespiratory diagnoses between (1) the two reference weeks and (2) the two hospitals.[19] The groups were found to be highly homogeneous; therefore, all results reported comprise pooled data. Confidence intervals (CIs) were computed for all relative proportions using the method of Gart and Nam.[20]

Finally, summary mortality data (obtained from the California Department of Health Services, Health Data and Statistics Branch) for Richmond, San Pablo, and El Sobrante (another small community potentially affected by the smoke) for calendar year 1988 were reviewed to ascertain whether respiratory-related deaths increased during or shortly after the fire period.

Although the smoke was visible for miles, there were unfortunately no relevant air quality data to analyze in conjunction with the health outcome information. The local air pollution control district's closest fixed-site monitor was west and upwind of the plume; the only 24-hour particulate matter sample (measured as total suspended particles) taken at that site during the fire week (on July 14) showed a reading of 52 $\mu g/m^3$, which was slightly greater than readings from samples taken 6 and 12 days earlier (46 $\mu g/m^3$ and 40 $\mu g/m^3$, respectively). No supplemental air monitoring was conducted.

Results

Hospital Survey

There were 489 charts abstracted for the four periods, representing 98.9% of all patients identified from emergency room logbooks and hospital admission records. Of these charts, 451 were for emergency room visits only, 30 were for emergency room visits resulting in hospital admission (counted as both emergency room visits and admissions in the analysis), and 8 were for direct hospital admissions. The distribution of visits and admissions by period is presented in Table 1. The numbers of daily respiratory-related emergency room visits are shown in Figure 1. (There were no differences in numbers of nonrespiratory-related emergency room visits during those periods.)

The ratios of proportions of specific diagnostic categories for emergency room visits are presented in Table 2. Emergency room patients were 1.4 times more

likely to receive an eligible respiratory diagnosis during the fire period than during the reference periods. Diagnoses of lower respiratory conditions (RP = 1.55) were increased to a greater extent than those of upper respiratory conditions (RP = 1.20). Among lower respiratory conditions, diagnoses of asthma, bronchitis, and pneumonia were all elevated. The ratio of proportions for conjunctivitis was increased but was not statistically significant (data not shown). We noted no age-related differences in emergency room visits for particular respiratory diagnoses during the fire period compared with the reference periods (data not shown). The proportion of emergency room visits with respiratory diagnoses but without any corroborating physical findings (i.e., ineligible visits) increased 4.05-fold during the fire period; this increase was highly significant (95% CI = 1.92, 8.52).

For hospital admissions, the proportion with diagnoses of respiratory-related conditions was elevated during the fire period, but the confidence interval included unity (RP = 1.77; 95% CI = 0.91, 3.45). Because of the small number of hospitalized patients, we did not calculate ratios of proportions for individual diagnoses.

Community Mortality Data

In the Richmond, San Pablo, and El Sobrante areas, there were no deaths from respiratory causes in the week preceding the fire, one such death during the fire period, four during the week after the fire had been extinguished, and three the following week. All-cause mortality for these weeks totaled 16, 11, 17, and 17, respectively. During calendar year 1988, weekly totals for respiratory causes of death ranged between zero and six (mean = 2.4, SD = 1.5); and for all causes, between 11 and 39 (mean = 23.1, SD = 6.0). Visual inspection of the data indicated that there was no obvious increase in mortality during the 3 weeks after the fire started (data not shown).

Discussion

In this survey, moderate increases in the proportion of hospital visits due to respiratory conditions were found during a 1-week period when an urban population was exposed to substantial quantities of structural fire smoke. However, only the ratio of proportions for asthma was significantly elevated.

Finding an increased proportion of visits for lower respiratory conditions and for asthma in particular was not unexpected, given that smoke, chemical irritants, and airborne particles can all provoke bronchoconstriction.[11-13] In this

study, the vast majority of visits for asthma (96%) during the fire period were made by patients with a previous history of this condition. Thus, the increased ratio of proportions for asthma was not due mainly to isolated episodes of bronchospasm, although such episodes can occur in association with smoke inhalation in people without a history of asthma.[16]

Our results regarding asthma are consistent with a recent report on the impact of forest fire smoke on the general population.[4] However, in that report (which used an emergency room survey design similar to the one reported here) the authors also found significant increases in emergency room visits for upper respiratory conditions. The disparity in results may be due to the substantially greater sample size in the forest fire study, differences in exposure intensity and duration, smoke composition, demographic characteristics, or emergency room triage and diagnostic patterns. Another recent report documenting the health impact of an urban wildfire found that nearly a third of fire-related emergency room visits were for bronchospastic reactions.[5]

Numerous temporal, economic, and individual behavioral factors affect the use of emergency medical services and limit the ability of hospital-based surveys to estimate community effects of acute exposure to smoke or other pollutants. Temporal variation in hospital usage patterns could lead to the selection of inappropriate reference periods and inaccurate estimations of effect. We tried to control for these factors by selecting remote and recent reference periods that paralleled the fire period (i.e., that began on the same day of the week), and by comparing the proportion of visits due to respiratory causes rather than the absolute numbers of respiratory-related visits.

In addition, hospital-based surveys can overestimate an effect if the perception of illness severity or the motivation to seek treatment is increased during periods of exposure. This study was unique in that we tried to control for these factors by distinguishing visits that were corroborated by physical findings from visits that were not. This proved to be the single factor most strongly associated with the fire period, as the proportion of ineligible emergency room visits during that period was four times higher than that in the reference periods.

TABLE 2—Ratios of Proportions for Selected Emergency Room Diagnoses at Two Hospitals in Richmond, Calif, during a Major Urban Fire in 1988

Diagnostic Category	Ratio of Proportions (95% Confidence Interval)	Number of Visits: Fire Period	Number of Visits: Reference Periods
All respiratory conditions[a]	1.40 (1.14, 1.73)	138	182
All upper respiratory conditions	1.20 (0.86, 1.68)	53	81
Upper respiratory infections	1.14 (0.66, 1.95)	21	34
All lower respiratory conditions	1.55 (1.17, 2.05)	85	101
Asthma	1.60 (1.09, 2.35)	47	54
Bronchitis	1.64 (0.98, 2.95)	24	27
Pneumonia	1.84 (0.59, 5.69)	6	6
Ineligible visits for respiratory complaints	4.05 (1.92, 8.52)	22	10

[a]Eligible emergency room visits only (see explanation in test), fire period compared with two pooled reference periods.

Conversely, hospital-based surveys may underestimate an effect if most illnesses associated with exposure are relatively mild or if the exposed population has access to other health care services. The influence of these factors limits the sensitivity of hospital-based surveys in estimating the overall public health impact of acute exposures. Our results therefore probably represent a conservative estimate of overall respiratory morbidity in the smoke-exposed areas. In addition, some of the patients presenting during the fire period were probably not exposed to the smoke since the catchment areas of these hospitals also extend to the east and south of the plume. Thus, the case mix of respiratory complaints during the fire period would have included both exposed and unexposed individuals, resulting in a bias toward the null in the estimates of the ratios of proportions.

All-cause mortality and respiratory-related deaths in the cities of Richmond, San Pablo, and El Sobrante during the fire period and subsequent weeks were well within the usual weekly trends for calendar year 1988. Thus, the fire's impact on acute respiratory morbidity was not reflected in the area's mortality statistics. Nevertheless, smoke exposure may have contributed to the demise of individual patients.

Some, if not most, of the respiratory morbidity associated with exposure to smoke from the warehouse fire might have been prevented by appropriate interventions—for example, official advisories to persons with preexisting respiratory disease, establishment of a shelter in a part of the county unaffected by the smoke, or possibly more aggressive efforts to extinguish the fire. The Richmond–San Pablo area contains a large oil refinery and other chemical production and storage facilities, and local authorities' emergency planning has focused almost exclusively on responses to inadvertent toxic gas releases. Had the fire occurred in a chemical storage facility (as opposed to a supermarket warehouse), a more vigorous response to protect public health, presumably including evacuation, would have been triggered. In situations in which prolonged general population exposure is predictable (as was the case here), organized protective measures should be undertaken expeditiously to prevent acute respiratory morbidity, particularly among persons with preexisting disease. □

Acknowledgments

We would like to acknowledge the invaluable assistance of the medical records staffs of Kaiser and Brookside hospitals in identifying and retrieving hospital charts for review. We would also like to acknowledge Marian Gentry, RN, (Contra Costa County Department of Health Services) and the late Dr Charles Gardipee, who helped review and abstract medical records.

Dioxins and Dibenzofurans in Adipose Tissue of the General US Population and Selected Subpopulations

John E. Orban, PhD, John S. Stanley, PhD, John G. Schwemberger, MS, and Janet C. Remmers, MS

ABSTRACT

Objectives. The Environmental Protection Agency's National Human Adipose Tissue Survey (NHATS) was conducted in fiscal year (FY) 1987 to (1) estimate average concentrations of polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) in the adipose tissue of humans in the US population, (2) identify differences in average concentrations among subpopulations, and (3) compare average concentrations with those from the FY 1982 NHATS.

Methods. Population estimates of the average levels of PCDDs and PCDFs were established on the basis of 865 human adipose tissue specimens collected in FY 1987. Average levels among subpopulations were compared.

Results. The average concentration of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin in the adipose tissue of the US population was 5.38 pg/g, increasing from 1.98 pg/g in children under 14 years of age to 9.40 pg/g in adults over 45. The effect of age was significant for nine compounds. Regional differences in the levels of 2,3,4,7,8-pentachlorinated dibenzofurans were statistically significant, but there were no significant differences associated with sex or race.

Conclusions. The survey provides a baseline of average levels of PCDDs and PCDFs in the adipose tissue of humans in the US population. (*Am J Public Health.* 1994;84: 439–445)

Introduction

The potential for human exposure to polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) has been extensively studied over the past several years. The PCDDs and PCDFs are recognized as ubiquitous contaminants in many areas of North America and have been determined to originate from numerous sources, including the emissions from incineration sources (municipal, hospital, and hazardous waste incinerators), effluents and solid wastes from pulp and paper processing, metal reclamation, petroleum refining, wood preservation, and the production of specific chlorinated chemicals. The PCDDs and PCDFs are stable lipophilic compounds and, as a result, persist in the environment and bioaccumulate. Human exposure can occur through a number of pathways via inhalation, ingestion, or dermal contact.

The presence of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) in human tissues was first reported as a result of investigations of human exposures to the herbicide Agent Orange.[1–9] As information was developed on the presence of PCDDs as by-products from other processes, a number of studies were initiated to assess the potential for human exposure to these compounds. These studies have included the evaluation of Vietnam veterans exposed to Agent Orange[1–9]; residents of Seveso, Italy, following the explosion of a trichlorophenol production plant[10,11]; residents of Times Beach, Mo, exposed to contaminated oil spread on roads and common areas[12–15]; individuals exposed to polychlorinated biphenyl fires[16]; of consumers of contaminated food products[17]; and workers from chemical production facilities.[18–20] Most of these studies focused on comparing levels of PCDDs and PCDFs in tissues from both exposed and nonexposed populations; a few focused on general populations, but these studies were limited in size and scope.[21–27]

One unique monitoring program for assessing human exposure to potentially toxic compounds is the National Human Adipose Tissue Survey (NHATS), operated since the early 1970s by the US Environmental Protection Agency (EPA). Human adipose tissues are obtained through a network of pathologists and medical examiners to provide a representative sample of the general US population. Preliminary data on the levels of PCDDs and PCDFs in this population were previously generated using NHATS tissue samples collected in fiscal year (FY) 1982.[28–30]

The NHATS specimens from the FY 1987 collection have also been analyzed for PCDDs and PCDFs, and a study design similar to that employed in FY 1982 was used. This paper describes the objectives, sampling design, and analytical efforts required to achieve the general US population estimates, and it presents the estimated average concentrations of specific PCDD and PCDF isomers for the various demographic

Caucasian	707	82	8	100	83
Mixed[b]	...	...	40	...	...
Non-Caucasian	158	18	0	0	17

[a]The percentage of composites in each sex and racial group is calculated from the total number of pure composites. For example, 16 of the 31 (52%) pure sex composites contain only specimens from male donors.

[b]A mixed composite contains specimens from both male and female donors or both Caucasian and non-Caucasian donors.

populations studied. Further details on the FY 1987 NHATS are available in an EPA final report.[31]

The specific objectives of the FY 1987 NHATS study were as follows:

- To estimate the average concentrations of PCDDs and PCDFs in the adipose tissue of humans in the general US population and various demographic subpopulations.
- To determine if there are significant differences among the average concentrations of PCDDs and PCDFs in the adipose tissue of individuals from different demographic subpopulations as defined by the individuals' geographic region, age, race, and sex.
- To compare the estimated average concentration levels of PCDDs and PCDFs found in the FY 1987 NHATS with estimates from the FY 1982 NHATS.

Methods

Study Design

The FY 1987 NHATS used a multistage sampling plan to collect human adipose tissue specimens from October 1986 through September 1987. Because of the invasive nature of the process required to collect the adipose specimens from living persons, the sampling population was limited to cadavers and surgical patients.

The 48 conterminous states were stratified into 17 geographical areas defined by the intersection of the 9 US census divisions and the 10 EPA regions. Although the sampling effort was divided among 17 geographic strata, the strata were later combined into the four US census regions (Northeast, North Central, South, and West) to simplify the presentation of results.

A sample of metropolitan statistical areas was selected with probabilities proportional to each area's population. Forty-seven such areas were selected from 14 of the 17 sampling strata for the FY 1987 NHATS; areas were not selected from the other 3 sampling strata (Arizona-Nevada, Idaho, and New Mexico) because of their small population size.

One or more cooperators (hospital pathologists or medical examiners) from each metropolitan statistical area supplied tissue specimens using quotas based on categories defined by the donor's age group (0 to 14 years, 15 to 44 years, and 45+ years), race (Caucasian and non-Caucasian), and sex. The subquotas are proportional to the 1980 US census population counts for each sampling stratum. The donors and tissue specimens were selected in a nonprobabilistic manner by the cooperators.

The guidelines for collecting specimens from cadavers specify that the death should have been caused by sudden traumatic injury such as cardiac arrest, car accident, or gunshot wound. Also, institutionalized individuals, persons known to be occupationally exposed to toxic chemicals, persons who died of pesticide poisoning, and persons suffering from cachexia were excluded from NHATS.

Interpretation of the statistical estimates derived from the NHATS data depend on several assumptions: (1) that the concentrations of toxic substances in the adipose tissue of cadavers and surgical patients are comparable to those in the general population; (2) that no significant bias is introduced by selecting only urban hospitals and medical examiners (i.e., those located in metropolitan statistical areas); and (3) that no systematic bias is introduced by the fact that the cooperators are not randomly selected and the donors and specimens are nonprobabilistically sampled according to prespecified quotas.

Of 956 specimens collected by the cooperators in FY 1987, 865 were designated for chemical analysis. Some specimens were excluded from the analysis because several cooperators exceeded their quotas for specimens in specific age-race-sex categories.

Prior to chemical analysis, each of the 865 "design" specimens were assigned to 48 composite samples. The total number of composite samples was limited by the budget for chemical analysis. Using composite samples helps to minimize the random effects of sampling error because the concentration of a target analyte in the composite sample represents the average concentration for individuals contributing specimens. Compositing criteria were established to achieve the study objectives of estimating and comparing average concentrations in selected subpopulations. These criteria specified that composites should be created using only specimens from donors in the same age group and the same US Census Division; however, composites could also be created using specimens from donors of different sexes or race groups.

Table 1 presents the numbers of specimens collected and of composite

samples analyzed within each category of the four analysis factors (geographic region, age, race, and sex). The percentages of total specimens collected and of total composites analyzed are also presented, along with the corresponding population percentages from the 1980 US Census. The statistical treatment of the data included adjustments to account for the differences between the population percentages and the percentages of specimens collected and composites analyzed.

In accordance with the abovementioned criteria, each composite sample is composed entirely of specimens from donors of a specific geographic region and age group. This ensures maximum precision for estimating differences in body burden levels among populations from different geographic regions and age groups.

The percentages of specimens from different donor sex and racial groups in the composite samples vary across the design depending on the actual collection of specimens within specific demographic subpopulations. In particular, it was not always possible to create composite samples containing only specimens from the same sex or race group. Seventeen of the 48 composites contained specimens from both sexes and 40 contained specimens from both race groups. However, it was still possible to estimate average concentrations for different sexes and racial groups by using the percentages of specimens from each demographic subpopulation as covariates in the statistical analysis.

Sample Preparation and Chemical Analysis

The 48 composite samples were prepared in the analysis laboratory to determine low picogram-per-gram (parts per trillion, ppt) levels of PCDDs and PCDFs using high-resolution gas chromatography/high-resolution mass spectrometry. Aliquots of individual specimens were combined according to the compositing design derived from statistical requirements of the study. Each of the resultant 48 composite samples was assigned a unique identification number and then randomly assigned to one of five sample analysis batches, along with the quality control samples (spiked and unspiked) that were prepared from human adipose tissue.

The sample preparation and chemical analysis procedures are described in detail in the EPA's final report.[31] The procedures were used to determine the tetrachloro through octachloro analogs of 2,3,7,8-substituted PCDDs and PCDFs. The quality control specimens incorporated with the sample batches allowed the method performance to be thoroughly assessed. Details of the quality control procedures and method performance results have been previously reported.[27,31]

Analysis

The statistical model applied to the composite sample data assumes that the four analysis factors (census region, age, sex, and race) have fixed additive effects on the average PCDD and PCDF concentrations in the specimens. This assumption creates 48 subpopulations defined by the $4 \times 3 \times 2 \times 2$ unique binations of categories. Because the composite sample concentration represents the average concentration of the contributing specimens, this assumption also results in a model for composite samples in which the measured concentration is also a linear function of the parameters associated with the effects of each of the four analysis factors.

There are also three ancillary factors that have random effects on NHATS data: (1) sampling of metropolitan statistical areas, (2) sampling of individuals within metropolitan statistical areas, and (3) measurement of analyte concentrations in the composite samples. The first two ancillary factors have random effects on the actual concentrations in individual specimens. These include the effects of selecting donors as well as of selecting specimens from individual donors. The third factor has a random effect on the measured concentrations of composites.

The method of iteratively weighted generalized least squares was used to estimate the model parameters,[32] which in turn were used to calculate predicted concentrations for each of the 48 subpopulations. Finally, marginal population averages for the different analysis categories were estimated by taking weighted averages of the appropriate predicted concentrations. Standard errors were calculated for each of the marginal averages.

Hypothesis tests were performed using the likelihood ratio method to determine if average concentrations differ significantly by any of the geographic or demographic factors. For example, the hypothesis that average concentration levels do not differ among the four census regions was tested against the alternative hypothesis that there is at least one pair of regions for which the average concentrations are different. Similar tests were performed for the effects of age, sex, and race.

The likelihood ratio method assumes that sampling and measurement errors are normally distributed. The additive effect of compositing specimens suggests that this assumption is justified because specimen sampling errors are averaged in the composite sample. Analysis of the residuals from the fitted model confirmed that the normal distribution of errors was a reasonable choice.

Results

The target compounds for the FY 1987 NHATS included 7 PCDDs and 10 PCDFs. However, statistical analyses of population averages and demographic effects were performed only on compounds that met two criteria: (1) their chemical analyses had to satisfy preestablished data quality objectives for at least 30 of the 48 composite samples, and (2) they had to be detected in at least 50% of the composite samples meeting those objectives. The data quality objectives were based on expected ion ratios (±20%), absence of interferences, and acceptable internal standard recovery (40% to 150%). Only data that met all the objectives were included in the statistical analysis.

For each of the 17 target compounds, Table 2 presents the number of composites meeting the data quality objectives, the average detection limit, and the percentage of composites in which the compound was detected. Six PCDDs (1,2,3,4,7,8-hexachlorodibenzo-*p*-dioxin [HxCDD] and 1,2,3,6,7,8-HxCDD are combined because they could not be separated in the chemical analysis) and three PCDFs met the criteria for conducting the statistical analyses. Each of these nine compounds met the data quality objectives for at least 32 composites and were detected in at least 92% of the composites. Also presented in Table 2 are the minimum, median, and maximum measured concentrations of the 17 target compounds found in the composite samples. The concentrations in the composite samples represent average concentrations of approximately 18 individual specimens used to create each composite. Therefore, the range of concentrations among individuals in the general population is expected

to be much greater than that observed for the composite samples.

Population Estimates

Table 3 presents the estimated average concentrations of the six PCDDs and three PCDFs noted above that met the criteria for analysis. Averages are provided for the entire US population as well as for the categories defined by the four analysis factors. Also presented is the relative standard error (percentage) for each estimate. The relative standard errors for the estimates of national average concentrations were 6% or less for the dioxins and 13% or less for the furans. All estimates were adjusted for population percentages based on the 1980 US census.

The average concentration of 2,3,7,8-TCDD in the US population is estimated to be 5.38 pg/g (±6%). The estimates for various subpopulation averages are presented even if the effects of the factors were not found to be statistically significant. For example, the regional estimates of 2,3,7,8-TCDD average concentrations range from 4.54 pg/g in the West to 6.02 pg/g in the Northeast. However, the differences among regions for this analyte were not found to be statistically significant.

The age group estimates in Table 3 suggest that the concentrations of nearly all analytes increase with the age of the donor. Notice that the highest concentration of each analyte occurs in the oldest age group. In fact, the hypothesis tests confirmed that there are statistically significant differences among age groups for all nine analytes.

Also presented in Table 3 are the International Toxicity Equivalents (I-TEQs) calculated according to the International Toxicity Equivalency Factor (I-TEF) method.[33] This method, adopted by EPA, is a biologically based procedure for estimating risks associated with exposures to complex mixtures of PCDDs and PCDFs. The I-TEQ is calculated as the sum of the I-TEF values times the estimated concentrations of the specific PCDDs and PCDFs. The isomers in Table 2 are assigned I-TEF values ranging from 0.001 to 1.0. The largest values are assigned to 2,3,7,8-TCDD (I-TEF = 1.0) and to 1,2,3,7,8-pentachlorodibenzo-*p*-dioxin (PeCDD) and 2,3,4,7,8-pentachlorinated dibenzofuran (PeCDF) (I-TEF = 0.5). All other isomers have I-TEF values of 0.1 or less.

In Table 3 the I-TEQs were calculated for the entire US population and for the various subpopulations. The calculations used the predicted average concentrations within each subpopulation for the nine isomers analyzed statistically. Because there were insufficient data on the remaining isomers to estimate average concentrations within each subpopulation, the simple average composite concentrations were used in the I-TEQ calculation. The isomers that were not statistically analyzed accounted for approximately 4% (I-TEQ = 1.1) of the total I-TEQs.

Because the statistical uncertainties of the I-TEFs have not been determined, Table 3 does not list the relative standard errors for the I-TEQs. However, they are expected to be slightly higher than those listed for 2,3,7,8-TCDD.

Analysis of Demographic Factors

Statistical hypothesis tests were performed on each of the target analytes to determine if there are statistically significant differences in average concentrations between individuals from different geographic regions, age groups, sex groups, and race groups. Table 4 lists the attained significance level—the smallest significance level that will refute the hypothesis that there are no differences between population averages—from the statistical tests associated with the four

[b]International Toxicity Equivalent (I-TEQ) includes an adjustment of 1.1 based on average composite concentrations of seven additional PCDFs.

analysis factors. For example, the differences among estimated averages of 2,3,7,8-TCDF in the four census regions could only be considered significant at the .15 level of significance. On the other hand, the differences in age group averages are significant at the .002 level. A 5% (.05) level of significance is generally the level used to declare statistical significance.

It is clear from Tables 3 and 4 that there are statistically significant differences among the average concentrations in the three age groups. As previously noted, the highest concentration of each analyte is found in the oldest age group (45+ years) and, except for TCDF, the lowest is found in the youngest age group (0 to 14 years). The only other statistically significant finding, at the .05 level of significance, was that there are regional differences in the average concentrations of 2,3,4,7,8-PeCDF. The average concentration in the western census region was estimated to be 4.49 pg/g compared with the national average of 9.70 pg/g. The highest average concentrations of 2,3,4,7,8-PeCDF were found in the Northeast (13.7 pg/g).

The differences in the estimated average concentrations between Caucasian and non-Caucasian and between male and female donors were not statistically significant for any of the modeled compounds.

Comparison of FY 1982 and 1987 NHATS Studies

One of the objectives of the FY 1987 NHATS study was to compare the levels of PCDDs and PCDFs with the baseline levels established in the FY 1982 NHATS study. The earlier NHATS results were based on the analysis of 46 composite samples created from 763 specimens. The study designs of the two studies were similar except there were 47 metropolitan statistical areas in the FY 1987 design compared with 35 in FY 1982; however, 30 of those 35 areas were included in the later survey.

The major differences between the FY 1982 and 1987 studies were the result of advances in the analytical methodology. The most significant change involved the use of additional internal quantitation standards. There were two internal standards used in FY 1982 and nine in FY 1987. As a result, the compounds that are most directly comparable between the two studies are 2,3,7,8-TCDD, and 2,3,7,8-octachlorodibenzo-p-dioxin (OCDD).

Figure 1 is a graphical representation of the demographic profiles of 2,3,7,8-TCDD from the FY 1982 and 1987 NHATS studies. The estimated average concentrations within each demographic subpopulation are connected with straight lines. The vertical lines define approximate 95% confidence intervals of the estimates. Estimated national averages with 95% confidence intervals are also plotted.

The statistical analysis reveals that there was no significant difference between the national average concentrations of 2,3,7,8-TCDD in human adipose tissue determined in the FY 1982 and 1987 NHATS studies. Also, there were no significant differences in the profiles with respect to region, sex, and race. On the other hand, only the FY 1987 NHATS demonstrated that the levels of 2,3,7,8-TCDD increase consistently with

the age of the donors. The average concentration in the later NHATS increases from 1.98 pg/g in the youngest group to 9.4 pg/g in the oldest. Smaller differences exist between the age group averages from the earlier NHATS.

Similar results were obtained in comparing OCDD levels between FY 1982 and FY 1987. The estimated national average concentration of OCDD in FY 1982 was 768 pg/g with a standard error of 79.7. The FY 1987 national estimate was 724 pg/g with a standard error of 28.6.

Discussion

The FY 1987 NHATS established nationwide and regional estimates of average PCDD and PCDF concentrations in human adipose tissue. Although the accuracy of these estimates depends on the extent to which cadavers and surgical patients represent the general population, NHATS is the most comprehensive study of PCDD and PCDF exposures in the general population performed to date.

The national estimate of 5.38 pg/g for 2,3,7,8-TCDD in human adipose tissue obtained in NHATS compares favorably with estimates derived in recent studies[12,14,15,21,34] that focus on regional populations. The studies report average concentrations ranging from 4.6 pg/g in California[25] to 8.2 pg/g in New Jersey and Missouri.[34] However, most of the studies did not use specimens from donors that were representative of the general population in terms of age; in particular, most studies did not include specimens from donors under 14 years of age. This, along with the differences in sample collection periods, may explain the slightly higher reported concentrations compared with those in the FY 1987 NHATS.

The FY 1987 NHATS demonstrated that the average body burden levels of PCDDs and PCDFs in the general population increase with age. For example, the average concentration of 2,3,7,8-TCDD in adipose tissue was found to increase at an average rate of 0.83 pg/g per decade for individuals under age 31 and at an average rate of 1.52 pg/g per decade for the older population. Other studies[12,15,21] have estimated the rate of increase to be approximately 2.0 pg/g per decade within older populations.

While age was found to be a significant factor in predicting the average levels of PCDDs and PCDFs in adipose tissue, there was no statistical evidence of differences in the average levels for populations representing different sexes and racial groups nationwide. However, the NHATS could not adequately examine the effects of these factors on a regional basis. Studies in California[25] and Missouri[12] have found statistically significant differences in the average levels of 2,3,7,8-TCDD among men and women.

The human health risk of exposures to PCDDs and PCDFs is of great concern, but it is a topic of much debate.[35] A recent cohort study of exposed workers[36] suggests the possible association between exposure to 2,3,7,8-TCDD and increased mortality from soft tissue sarcoma and cancers of the respiratory system. Although the results are inconclusive, it is clear that future research must involve the determination

of the exposures to PCDDs and PCDFs as well as the incidence of adverse health effects. The FY 1987 NHATS provides important baseline results that will be needed for this research. □

Acknowledgments

We are grateful to Ms Cindy Stroup and Dr Joseph Breen of the EPA's Office of Pollution Prevention and Toxics for their guidance and support for this work. Also we recognize the technical contributions of Dr Robert Lordo, Dr Ron Menton, Ms Tamara Collins, Ms Pam Hartford, and Ms Claire Matthews of Battelle Memorial Institute; Ms Karin Bauer, Mr Paul Cramer, and Dr Jerry Flora of Midwest Research Institute; Ms Barbara Leczynski of EPA's Office of Pollution Prevention and Toxics; Dr Al Unger of SAIC; and Mr John Rogers of Westat.

Pesticide Exposures, Cholinesterase Depression, and Symptoms among North Carolina Migrant Farmworkers

Stephen Ciesielski, PhD, MD, Dana P. Loomis, PhD, Susan Rupp Mims, MD, and Annella Auer, MPH

ABSTRACT

Objectives. We conducted a clinic-based study of erythrocyte cholinesterase levels, pesticide exposures, and health effects among farmworkers and nonfarmworkers to determine risks for exposure and associated morbidity.

Methods. Two hundred two farmworkers and 42 nonfarmworkers were recruited sequentially at two community health centers. Erythrocyte cholinesterase levels were measured colorimetrically. Questionnaires obtained data on demographics, occupational history, exposures, and symptoms.

Results. Cholinesterase levels were significantly lower among farmworkers (30.28 U/g hemoglobin) than among nonfarmworkers (32.3 U/g hemoglobin). Twelve percent of farmworkers, but no nonfarmworkers, had very low levels. Farmworkers applying pesticides also had lower cholinesterase levels. One half of farmworkers reported being sprayed by pesticides and working in fields with an obvious chemical smell. Of reported symptoms, only diarrhea was associated with cholinesterase levels. Reported exposures, however, were strongly associated with symptoms.

Conclusions. Farmworkers reported many pesticide exposures that violate state and federal regulations. Farmworkers had cholinesterase levels significantly lower than those of nonfarmworkers, although only spraying pesticides was associated with very low levels. (*Am J Public Health.* 1994;84:446–451)

Introduction

Exposure to cholinesterase-inhibiting pesticides such as organophosphates and carbamates is considered a major health problem for the 2.5 to 5 million farmworkers in the United States and the 80 000 farmworkers in North Carolina.[1–6] Clinical manifestations of such exposure are extremely diverse.[7–9] Long-term exposure has been implicated in several types of cancer, teratogenic effects, sterility, spontaneous abortion, and cognitive deficits.[10,11] Major poisonings among farmworkers are fairly well characterized, but the health effects of routine, smaller exposures are uncertain. Previous studies, although limited by small sample size and inadequate comparison groups, revealed depressed cholinesterase levels in farmworkers,[12–16] the pathophysiological significance of which remains unclear. Thus, we conducted a clinic-based study of farmworkers and nonfarmworkers in North Carolina to assess pesticide exposure, the symptoms occurring among exposed workers, and the effect of simple measures to protect against exposure.

Methods

Subject Selection

Every third patient presenting to two community health centers was an eligible subject. Those performing farmwork for 1 week of the previous month (i.e., those with the potential for occupational exposure) were eligible for the farmworker group. Those who had never performed migrant farmwork were eligible for the unexposed nonfarmworker group. Two hundred two farmworkers and 42 nonfarmworkers participated; nonresponse was 4% (8) for farmworkers and 5% (2) for nonfarmworkers. There was no attrition. Informed consent was obtained from subjects in their preferred language.

Measurement of Symptoms and Pesticide Exposure

Pretested, verbally administered questionnaires obtained information about demographic characteristics, work history, occupational pesticide exposure within 1 month of enrollment, and symptoms within 1 week of enrollment. Nonfarmworkers were questioned about domestic and occupational exposure to pesticides. Because exposure to cholinesterase-inhibiting pesticide produces characteristic biologic effects,[8–10] a fairly comprehensive range of symptoms was included in the questionnaire. Two symptoms thought not to be associated with exposure—increased nail friability and dysgeusia (altered taste perception)—were also included to assess the extent of recall bias.

Erythrocyte Cholinesterase Measurement

Cholinesterase depression represents an unambiguous indication of exposure to cholinesterase-inhibiting pesti-

cides as well as a biologic effect of such exposure.

Five microliters of blood were obtained by finger prick. Hemoglobin and acetylcholinesterase activity were measured with the Test-Mate OP Kit (EQM Inc, Junefield, Ohio). This field assay uses a modified Ellman method[17] and has received extensive field and lab testing.[18–21] Acetylcholinesterase activity, measured as absorbance, was corrected for ambient temperature and hemoglobin. Replicate tests were performed on subjects with acetylcholinesterase levels below 25 U/g hemoglobin. Field staff tested themselves daily as an external quality control. Subjects' results from days on which the operator's acetylcholinesterase level varied by more than 10% from the operator's mean were not included in the final analysis.

Symptomaticity may occur only with severe acetylcholinesterase depression.[8] Therefore, measurement of the frequency of adverse effects in a population may depend more strongly on the proportion with very low acetylcholinesterase levels than on those whose levels represent the population mean. To account for this possibility, cholinesterase levels were dichotomized into normal and low categories as well as treated on a continuous scale. The cutpoint for these categories was one standard deviation below the mean of the nonfarmworker group.

Data Analysis

Like many biochemical markers, acetylcholinesterase inhibition can be viewed as a measure of either exposure or outcome. In the first part of the analysis, employment as a migrant farmworker was taken as an indicator of the potential for pesticide exposure, cholinesterase levels were examined among farmworkers and the comparison group of nonfarmworkers, and their mean cholinesterase levels were compared. In addition, odds ratios were used to compare the observed and expected numbers of "cases" with extremely low cholinesterase levels among farmworkers, deriving the expected numbers from the experience of the nonfarmworker comparison group.

Subsequent analyses focused on the relationship of acetylcholinesterase depression among farmworkers to specific occupational and behavioral indicators of potential exposure; nonfarmworkers could not, by definition, have had these exposures. Acetylcholinesterase levels for farmworkers who reported a given exposure or activity were compared with levels for farmworkers without that factor, and the data were treated in both continuous and dichotomous forms as before.

The third and final part of the analysis sought to identify symptoms associated with exposure. Instances of workers who reported a given symptom were treated as cases. Pesticide exposure was defined by both an extremely low acetylcholinesterase level and reported occupational exposure through using pesticides, being sprayed, or working in recently sprayed areas. For each symptom, odds ratios were used to estimate the ratio of observed to expected cases.

The statistical analysis was performed using the SAS system (SAS Institute, Cary, NC). Coefficients for linear regression models were estimated by least squares, with P values derived from standard F tests. Confidence intervals (CIs) for crude odds ratios were based on Woolf's method, and the Mantel-Haenszel chi-squared statistics were used for hypothesis testing.[22] Adjusted odds ratios were estimated by logistic regression.

Results

Both groups were demographically similar with regard to birthplace, but farmworker subjects were younger and more often male (Table 1).

Figure 1 shows the distributions of cholinesterase levels between the two groups. The mean acetylcholinesterase level of the farmworkers (30.18 U/g hemoglobin) was significantly lower than that of the nonfarmworkers (32.20 U/g hemoglobin; $P = .01$) (Table 2). No nonfarmworkers had acetylcholinesterase levels below 25.28 U/g hemoglobin (the lower limit of the nonfarmworker mean minus one standard deviation), while 24 (12%) of the farmworkers did ($P = .019$).

Many farmworkers reported occupational exposure to pesticides. One type of exposure derives from the application of pesticides. Forty-seven percent of

farmworkers reported being sprayed directly with pesticides or working immediately adjacent to rig spraying within 1 month prior to study enrollment (Table 3); 33% of these subjects reported subsequent illness. Fifty-one percent of the subjects reported working in fields with an obvious chemical smell. None of these reported exposures was associated with significantly lower acetylcholinesterase levels although among those reporting exposures was a consistently greater proportion of cases with acetylcholinesterase below 25.28 U/g hemoglobin.

In contrast, the mean acetylcholinesterase level of farmworkers applying pesticides was 2.7 U/g hemoglobin lower than that of other farmworkers ($P = .002$), and the odds ratio for the association of having extremely low acetylcholinesterase with applying pesticides was 4.2 (95% CI = 1.1, 16) (Table 3). There were no significant differences among the mean acetylcholinesterase levels of farmworkers employed in different crops.

A second type of exposure derives from pesticide residues and relates to potentially protective behaviors such as wearing gloves or washing hands (Table 4). Low acetylcholinesterase levels had little or no association with these exposures. The majority of subjects (58%) reported that handwashing water was not consistently available. Similar analyses that used linear and logistic regression models and adjusted for age, years in farmwork, demographic characteristics, and multiple exposures produced essentially the same results.

When the frequency of symptoms among farmworkers was examined with respect to acetylcholinesterase levels below and above 25.28 U/g hemoglobin, only diarrhea was substantially associated with lower levels (odds ratio = 3.1; 95% CI = 1.18, 8.0) (Table 5). However, 10 of the 16 symptoms had positive associations with reported exposure. Neither of the variables included to assess possible recall bias was associated with acetylcholinesterase levels, but dysgeusia did have an association of borderline significance with reported exposure (Table 5).

Discussion

To our knowledge, this is the largest epidemiological study to date of the health effects on farmworkers of exposure to cholinesterase-inhibiting pesticides. A clinic-based design was chosen to maximize inclusion of morbidity in order to examine the biologic relation between illness and acetylcholinesterase levels. The methodological difficulties in the epidemiological study of the health of migrant farmworkers relate primarily to worker transience and workplace conditions. Attrition complicates longitudinal study: in previous research, 74% to 83% of subjects were lost to observation within 1 to 3 years.[23,24] In cross-sectional studies, constraints on determining etiology are compounded by barriers to observational data collection and by the fact that workplace exposure and conditions may change daily.

Reliance on reported exposures poses obvious problems. Most farmworkers do not know to what pesticides they may be exposed. Moreover, although we saw no evidence of it, recall bias may cause overreporting of exposure among symptomatic subjects. Underreporting may be more common; state and federal regulations prohibit fieldwork before sprays have dried or dusts have settled,[25] but perceptible signs of reentry time violation may not exist. An obvious chemical smell indicates that pesticides remain suspended or liquid. Fifty percent of subjects reported exposure both to pesticide suspensions and to aerial or rig spraying, and one third of these subjects reported subsequent illness. Even allowing for substantial misattribution, it appears that occupational exposures to pesticides may routinely result in illness among farmworkers.

The most significant associations between occupational conditions and low acetylcholinesterase levels were demonstrated for workers applying pesticides. North Carolina regulations require that all individuals involved in the application of pesticides receive training and be licensed. No subjects who worked applying pesticides and who had low acetylcholinesterase levels were licensed.

The prevalence of protective behaviors was higher for those actions directly under the workers' control, such as the use of protective clothing. However, even individual protective behaviors such as washing are limited by occupational conditions such as the availability of water. Subjects' motivation to engage in protective behavior is indicated by the fact that as many subjects reported handwashing before eating as reported the availability of handwashing water. The unavailability of handwashing water (reported by 58%) is exactly the same as that obtained by a study conducted several years earlier,[23] suggesting that, despite promulgation of new field sanitation laws, lack of enforcement allows unsafe working conditions to continue.

Associations between exposure and low acetylcholinesterase levels can be examined without knowing the specific pesticides involved because no other significant environmental exposures lower *erythrocyte* cholinesterase.[26] As did earlier studies,[12–16] we found that farmworkers have lower acetylcholinesterase levels than nonfarmworkers. The difference in means was statistically significant, but its biologic meaning is uncertain. Of more probable importance is that 12% of farmworkers had levels below the lower limit of the nonfarmworker group. Since the nonfarmworkers were not really unexposed (all lived in heavily sprayed agricultural areas and many reported using pesticides on gardens or pets), the difference between a farmworker group and an unexposed group may be underestimated.

TABLE 3—Cholinesterase Levels and Occupational Exposures to Pesticide Application Reported by Farmworkers[a]

The health effects investigated all have multiple causes, many especially prominent in farmwork. Rashes result from plant allergens, dermatoses, sun, heat, infectious causes, and a variety of pesticides. Interactions with other health risks in farmwork may not only complicate diagnosis and study but also place farmworkers at greater risk. For example, dermatoses increase absorption of pesticides, and dehydration and poor nutrition increase their toxic effects.

Only minimal association was observed between low acetylcholinesterase levels and morbidity. However, a moderately strong association was observed with diarrhea, reported as one of the most common effects of such exposure.[27] Several explanations for this relative lack of association exist:

1. No morbidity resulted because acetylcholinesterase levels were not sufficiently depressed to cause appreciable illness. It is also possible that tolerance develops to acetylcholine or that production of acetylcholinesterase increases in the face of repeated exposure.[26]

2. Limitations of cross-sectional study design introduced time-related misclassification of exposure and/or outcomes. Collecting data on exposures in the previous month but on symptoms only during the previous week may have allowed acetylcholinesterase depression to continue but associated symptoms to resolve.

3. Changing exposure to cholinesterase-inhibiting pesticides and other pesticides causing similar symptoms by different mechanisms may obscure the relationship between exposure and illness. Also, since carbamates reversibly inhibit acetylcholinesterase, resolution of previously depressed acetylcholinesterase levels may have occurred before enrollment.

[c]Availability of handwashing water does not relate directly to residue exposure but directly limits the ability of individuals to accomplish protective behaviors related to the use of water for washing.
[d]For those who smoke.

Reported exposures, however, were strongly associated with reported symptoms. The results of the symptom variables included to assess recall bias suggest that such bias was minimal. Farmworkers who reported exposures were no more likely to report nail friability than those who did not, although dysgeusia was of borderline significance. However, dysgeusia may be indirectly related to exposure since it may result from sialorrhea or nausea.[28]

Given the evidence of exposures in excess of those permitted by federal regulations, of the depression of acetylcholinesterase levels, and of the associa-

[a]Low erythrocyte cholinesterase defined as below 25.28 U/g hemoglobin.
[b]Category of those exposed includes subjects reporting one of the following: (1) being sprayed directly, (2) working in fields near spraying, (3) working in fields with a chemical smell, or (4) mixing/applying pesticides.
[c]Crude odds ratios were obtained from Mantel-Haenszel chi-squared statistics.
[d]Muscular disorder includes weakness, muscle cramps, and muscle fasciculations.

tions between exposure and reported symptoms, it seems probable that morbidity results from these more routine types of pesticide exposure among farmworkers despite the relative lack of association with acetylcholinesterase depression. It is also possible that the cross-sectional nature of this study limited the identification of morbid sequelae. This conclusion is strengthened by anecdotal experience. The same acetylcholinesterase field assay was later used to diagnose pesticide-related illness in a farmworker clinic. Seventeen individuals with characteristic symptoms were tested; four had acetylcholinesterase levels below the lower limit of normal. Their acetylcholinesterase levels had increased for 3 to 4 successive weeks before the subjects were lost to follow-up; however, their symptoms had usually resolved within 1 week of exposure.

It is important that additional research be undertaken for several reasons. First, migrant health programs have begun to dedicate much of their extremely limited funds to pesticide issues despite uncertainty about the extent of health effects. Most funding goes to educational programs designed to change farmworker behaviors, although exposures leading to serious illness or death are not likely to be under workers' control. Second, this study only addresses acute and subacute neurotoxicity. Thus, the relationship between organophosphate and carbamate exposure and other serious health effects such as cancer remains controversial even though such outcomes may be the most significant health effect of pesticide exposure.[11] Cholinesterase testing may eventually serve a more important role in monitoring workers for long-term cancer risk than for short-term neurotoxicity.

Paradoxically, although pesticides are routinely regarded as a serious health risk for farmworkers, few if any migrant health clinics are capable, in terms of technology, diagnostic protocols, and logistics, of diagnosing pesticide-related illness. We strongly recommend that migrant health centers develop means of routine cholinesterase testing to improve both diagnosis of pesticide poisoning and descriptions of the nature and extent of pesticide-related illness among migrant farmworkers on a population level.

Although population parameters cannot be estimated, some conclusions can nevertheless be drawn from these results. First, many patients presenting to farmworker clinics may have had recent pesticide exposures exceeding those permitted by federal regulations. These patients often believe that such exposures have adversely affected their health. Second, depressed acetylcholinesterase levels are more often found among farmworker patients than among nonfarmworker patients. The clinical significance of these low acetylcholinesterase levels cannot be determined on the basis of these data. Finally, farmworkers' behavior suggests that they are motivated to reduce pesticide exposures but that their ability to do so is constrained by occupational conditions beyond their control. □

Acknowledgments

Funding for this study was provided by the North Carolina Primary Health Care Association (NCPHCA) in Cary, NC. Gratitude is expressed to Susan Sparrow, NCPHCA migrant specialist, to Noni Estelli for assistance with field work, to the Tri-County Community Health Center in Newton Grove, NC, and to Goshen Medical Center in Faison, NC.

AIDS Risk Reduction and Reduced HIV Seroconversion among Injection Drug Users in Bangkok

Don C. Des Jarlais, PhD, Kachit Choopanya, MD, MPHTM, Suphak Vanichseni, MD, MPH, Kanokporn Plangsringarm, BSc, Wandee Sonchai, BA, Manuel Carballo, PhD, Patricia Friedmann, MA, and Samuel R. Friedman, PhD

A B S T R A C T

Human immunodeficiency virus (HIV) seroconversion was studied in a group of 173 injection drug users in Bangkok, Thailand, who had been previously tested for HIV and were interviewed and retested in the fall of 1989. Ten percent of the group had seroconverted. Two factors protected against HIV seroconversion: having stopped sharing injection equipment in response to the acquired immunodeficiency syndrome (AIDS) and having a regular sexual partner. The association between self-reported deliberate risk reduction and reduced HIV seroconversion among persons continuing to inject illicit drugs indicates that injection drug users can change their behavior in response to AIDS and will accurately report on the behavior change, and that the changes can protect against HIV infection. (*Am J Public Health* 1994; 84:452–455)

Introduction

Human immunodeficiency virus (HIV) infection has been reported among injection drug users in over 50 different countries.[1,2] Large-scale risk reduction, followed by stabilization of HIV seroprevalence, has been observed among injection drug users in many cities, including New York,[3] Stockholm,[4] San Francisco,[5] Innsbruck,[6] Vienna,[7] and Edinburgh.[8] In all of these cities, however, the association between risk reduction and reduced HIV transmission has been shown only at the community level. To date, there have been no reported studies showing that practicing "safer injection" because of concern about acquired immunodeficiency syndrome (AIDS) reduces the likelihood of HIV seroconversion at the individual level. No study of syringe exchange to date has linked individual use of syringe exchange to a lower risk of HIV seroconversion.[9–13] Similarly, no study has yet shown a protective effect of bleach disinfection against HIV seroconversion at the individual level.[14]

The absence of an individual-level linkage between deliberate risk reduction and reduced HIV seroconversion reinforces the common belief that persons who continue to inject illicit drugs cannot change their AIDS risk behavior and that they will not accurately report their risk behavior. These beliefs have been cited by policymakers in the United States as a rationale for opposing AIDS prevention programs that involve legal access to sterile injection equipment.[15,16]

We report here evidence that deliberate AIDS risk reduction behavior has a protective effect on HIV seroconversion at the individual level among persons continuing to inject illicit drugs in Bangkok, Thailand. Transmission of HIV among injection drug users in Bangkok had been among the most rapid in any population. In studies of injection drug users attending drug abuse treatment clinics in Bangkok, seroprevalence increased from 1% in late 1987 to 15% in March 1988 to 43% in the fall of 1988.[17,18] As public health officials became aware of the spread of HIV among injection drug users in Bangkok, AIDS education/prevention programs were rapidly implemented, including prominent posters in drug abuse treatment clinics. Staff at these clinics encouraged injection drug users not to "share" injection equipment and to purchase sterile injection equipment at pharmacies (prescriptions are not required); educated injection drug users about

sexual HIV transmission; distributed condoms; and provided HIV testing and counseling. Since the fall of 1988, seroprevalence among in-treatment injecting drug users has stabilized: 45% were HIV positive in the spring of 1989[18] and 39% were HIV positive in the fall of 1989.[19] In the fall 1989 study, 92% of the subjects reported that they had changed their behavior to reduce the risk of developing AIDS, with 59% reporting that they had "stopped sharing" injecting equipment because of concern about AIDS.

Methods

In the fall of 1989, 601 injection drug users were recruited at the clinics of the Bangkok Metropolitan Administration drug abuse treatment system. Injecting within the past 2 months was required for study eligibility. Subjects were selected randomly from among persons who had been in treatment for at least 3 months (n = 342) and randomly from among persons who were entering the treatment system (n = 259). All persons asked to participate agreed to do so. At that time, the primary treatment regimen provided in these clinics was a 45-day methadone-assisted detoxification program, followed by aftercare counseling. (Methadone maintenance programming in Bangkok has since been greatly expanded.)

Informed consent was obtained, a risk behavior questionnaire was administered by trained interviewers, HIV test counseling was conducted, and a blood sample was obtained. The questionnaire was developed as part of a multisite World Health Organization study and emphasizes risk behavior in the 6-month period before the interview. Sera were tested for anti-HIV antibodies by double ELISA tests (Wellcome) with confirmation of positive results by Western blot assay (Pacific Health Care) at the Siriraj Hospital laboratory.

Two hundred sixty-three subjects reported that they had previously been tested for HIV, with 173 reporting that their most recent previous test was negative. Retesting of these 173 presented an opportunity to identify risk factors for HIV seroconversion.

Chi-square tests and multiple logistic regression (SAS statistical programs[20]) were used to test associations with HIV seroconversion.

Results

Table 1 presents selected demographic and drug history characteristics of the 173 subjects reporting a previous HIV-negative test. The mean time between most recent previous test and current test was 9.8 months (SD = 7.2; range = 1–32, median = 8).

Seventeen (10%) subjects had seroconverted by the fall of 1989. Bangkok Metropolitan Administration records were used to validate the previous HIV-negative test for all of these 17 subjects. Assuming that the seroconversions occurred midway between the most recent negative HIV test and the fall 1989 test gave an estimated HIV seroconversion rate of 12.5 per 100 person-years at risk for this sample (95% confidence interval [CI] = 7.6, 17.4).

The 17 subjects who had seroconverted were compared with the 156 subjects who remained seronegative on demographic, drug use, and sexual behavior variables. As shown in Table 2, the three variables that significantly distinguished the seroconverters were (1) having been incarcerated since starting drug injection (a risk factor); (2) reporting that they had "stopped sharing injection equipment in response to AIDS" (a protective factor); and (3) having a primary sexual partner (a protective factor) (a "primary" partner was defined for the subjects as a "regular, most important" sexual partner). The "stopped sharing" variable was constructed from an open format question: "Since you first heard about AIDS, have *you* done anything to avoid catching the virus yourself, or to prevent

TABLE 3—Multivariate Logistic Regression Analysis for HIV Seroconversion among Injection Drug Users in Bangkok

Factor	χ^2	*P*	Odds Ratio (95% CI)
Did not stop sharing injection equipment	6.475	.01	4.01 (1.38,11.66)
Lacks primary sexual partner	6.589	.03	4.17 (1.13,15.41)

Note. CI = confidence interval.

someone else getting it from you?" Subjects were coded as "having stopped sharing" if they responded to this question by reporting that they had "stopped sharing" injection equipment and if they also responded on the follow-up question that they had "maintained this behavior change."

Multiple logistic regression with backwards elimination was used to examine the statistical independence of the three factors associated with HIV seroconversion. (The wording for the two protective factors was reversed so that they were entered as risk factors.) Results are presented in Table 3; failure to stop sharing and lacking a primary sexual partner remained statistically significant.

Most of the risk behavior questions in the questionnaire asked about behavior in the previous 6 months, although many of the seroconversions may have occurred earlier. We therefore repeated the analyses using only the 103 subjects (10 seroconverters) who had tested negative within the 10 months before the fall 1989 testing (and thus presumably had seroconverted within the previous 5 months). To assess the possibility that recently tested nonconverters did not have sufficient time for seroconversion, the analyses were also repeated omitting the 19 subjects (1 seroconverter) who reported that their previous HIV-negative test was within 3 months before the fall 1989 HIV testing. The same pattern of relationships was found in these two subanalyses as for the 173 subjects. (Data available from the corresponding author.)

Discussion

In this study, injection drug users who reported practicing safer injection ("stopped sharing injection equipment") because of concern about AIDS were less likely to have seroconverted for HIV. The time period (1987 through 1989) covered by this study was a period of high rates of both new HIV infections and AIDS risk reduction among injection drug users in Bangkok. Concurrence of high rates of seroconversion and deliberate risk reduction may be an important factor in our ability to show a statistical association between the two processes.

Although lack of documentation of previous HIV tests for the nonconverters is a limitation of this study, the high accuracy of the test reports of the seroconverters and the generally high accuracy of reported HIV test results in another study of injection drug users[21] suggest that few subjects would report a previous test without having been tested.

The 12.5 seroconversions per 100 person-years at risk should *not* be considered as representative of the seroconversion rate among all injection drug users in Bangkok from 1987 through 1989. All subjects in this study would have known about AIDS from their previous HIV counseling and testing and thus would have had some opportunity to change their behavior before HIV seroconversion (although not necessarily before HIV infection). Given the rapidity of the spread of HIV among injection drug users in Bangkok,[19] it is likely that most of the individuals who became infected between 1987 and 1989 did so before they learned about AIDS.

It is not surprising that no specific sexual behavior was associated with HIV seroconversion. The great majority of injection drug users in Bangkok are male, and few have sexual partners who are injection drug users. At the time of this data collection, there were few HIV-infected persons other than injection drug users in the city.

Having a regular sexual partner—an indicator of social integration—had a protective effect against seroconversion in this study. A number of previous studies of injection drug users found that lack of social integration was associated with higher rates of HIV exposure and/or higher rates of risk behavior: being part of an ethnic minority group; being homeless; having a particularly low income; and residing in a shelter or boardinghouse.[22-26] The mechanisms through which these indicators of social marginalization are related to higher rates of risk behavior or higher rates of HIV infection have not been identified, but such relationships do exist in different national settings.

Reporting that one had stopped sharing drug injection equipment in response to AIDS was strongly associated with not seroconverting in this study. To our knowledge, this is the first time that self-reported deliberate AIDS risk reduction among persons continuing to inject drugs has been associated at the individual level with a reduced likelihood of new infection with HIV. These data provide evidence for the construct validity of self-reported AIDS risk reduction among injecting drug users. (The "validity" of a technique for measuring behavior or psychological/social characteristics refers to whether the technique actually measures what it purports to measure.[27] Construct or "predictive" validity is demonstrated when the measured behavior/characteristic is statistically associated with other behaviors/characteristics according to an explicit theoretical framework. Construct validity for measurement of AIDS risk behavior of injection drug users has been demonstrated through the many studies showing strong associations between self-reported risk behavior and HIV status. Valid measurement of behavior change is, however, a much more difficult task than valid measurement of recent behavior, so that it is important to separately demonstrate validity for self-report measurement of AIDS-related behavior changes.) This finding serves to increase confidence that injection drug users can and will change their behavior to reduce the chances of developing AIDS, that they can and will accurately report such changes in behavior, and that such changes in behavior can directly protect the individual drug injector against infection with HIV. □

Epidemiology Summer Program to Be Held at Tufts

The New England Epidemiology Institute will sponsor the 14th annual Epidemiology Summer Program, July 11 through July 29, 1994, at Tufts University's Medford, Mass, campus. The program includes methodological, statistical, and substantive courses intended for those seeking an introduction to modern epidemiological concepts, as well as for those desiring a review of recent developments in epidemiological thinking.

This year the Institute will be offering 1- and 2-week sessions, allowing participants to attend for 1, 2, or 3 weeks. The 2-week session will run from July 11 through July 22 and will include the theory and practice of epidemiology (introductory and advanced levels), basic biostatistics, regression methods, survival analysis, genetic epidemiology, nutritional epidemiology, epidemiology in developing countries, and clinical research. The 1-week session will run from July 25 through July 29 and will include an introduction to epidemiology, conducting epidemiological research, pharmacoepidemiology, epidemiological research in women's health, the biology and epidemiology of cancer, epidemiology in public health practice, perinatal epidemiology, and occupational epidemiology.

Invited faculty include teachers and researchers from leading universities. Registrants may receive graduate-degree credit or continuing education credits from Tufts University, Continuing Medical Education (AMA Category 1) through Tufts University Medical School, or Certification Maintenance from the American Industrial Hygiene Association.

For more information please contact the New England Epidemiology Institute, Dept PA-AJPH, One Newton Executive Park, Newton Lower Falls, MA 02162-1450; tel (617) 244-1200; fax (617) 244-9669.

Racial Differences in Rural Adults' Attitudes toward Issues of Adolescent Sexuality

Ronnie D. Horner, PhD, Kathryn M. Kolasa, PhD, RD, Thomas G. Irons, MD, and Kenneth Wilson, PhD

ABSTRACT

This study, based on a random sample of adults in a rural North Carolina county, demonstrates racial differences in rural adults' attitudes relating to adolescent sexual issues. Blacks were 50% more likely than Whites to indicate that public schools should provide general health care services, including pregnancy testing and treatment of sexually transmitted diseases, to teenagers; however, they were only half as likely as Whites to approve of sexual experimentation by adolescents. The local community's attitudes must be considered in the implementation of rural adolescent health programs, including acquired immunodeficiency syndrome education. (*Am J Public Health.* 1994;84:456–459)

Introduction

An increasing emphasis is being given to local community initiatives, such as public school–based programs, for educating adolescents about and assisting them to avoid the risks associated with premarital sexual activity, particularly pregnancy and infection with sexually transmitted diseases such as the human immunodeficiency virus (HIV).[1,2]

Adults' attitudes toward adolescent sexual activity and intervention programs influence the content and success of these programs.[3–7] However, this knowledge derives almost exclusively from urban studies. The few studies of rural populations have focused on the extent of adolescent sexual activity rather than adults' attitudes regarding such activity and possible intervention programs.[8–10] This report presents the results of a survey on attitudes regarding adolescent sexuality and related issues held by Black and White adults in a rural community.

Methods

This is a secondary analysis of data that were originally collected for an investigation of rural, southern adults' attitudes and beliefs regarding adolescent health issues, including adolescent sexual activity and pregnancy, sex education, and the provision of health services to teenagers through the county public schools. The survey was the first phase of a community-based intervention program aimed at reducing the number of teenage pregnancies in this rural North Carolina county, which has one of the highest rates of adolescent pregnancy in the state.[11]

The respondents were a random sample of adults (aged 18 years and older) stratified on age and sex. Telephone or in-person interviews were completed for 835 of the 1037 sampled households (80.5%). There were no systematic differences in responses based on type of interview, and respondents were sociodemographically representative of the county population. The interview schedule was pretested and revised until it was effective with respondents from all social backgrounds.[12]

The data analysis was based on the 801 respondents who were either White or Black. Individual questions and indexes composed of related questions (see Appendix) were analyzed. The data were summarized by proportions and means with standard deviations, and racial differences in responses were analyzed by chi-square tests or *t* tests. When significant racial differences were detected, the effect of race was assessed by logistic regression or analysis of covariance (for the indexes) adjusting for covariates shown by preliminary analyses to be potential modifiers of self-reported attitudes, including sex, age, marital status (married vs other), income, education (college vs other), place of residence (central community vs surrounding communities), political orientation (conservative vs other), and religiosity (attend church at least once a week vs less frequently). Because the unadjusted and adjusted results were consistent with few exceptions, which are noted, the former are presented for simplicity.

Results

Characteristics of Respondents

Black and White respondents differed in their sociodemographic charac-

teristics in the expected directions. Blacks were more likely to be women, to be unmarried, to have lower income, and to attend church at least weekly, but they were less likely to have attended college or to live in the central community of the county.

Provision of Health Services to Adolescents

Blacks and Whites agreed equally that public schools should provide health services to adolescents but differed significantly on the types of services to be provided (Table 1). Black respondents were about 50% more likely than Whites to believe that general health services and health services relating to sexual activity (e.g., pregnancy testing) should be provided. The indexes also indicated stronger support for these services by Blacks. The effect of race disappeared with adjustment for sociodemographic characteristics, political orientation, and religiosity only for provision of birth control products to girls, provision of child care instruction, and the Assistance with Personal Problems Index. There were no significant racial differences regarding provision of educationally related health services, such as the distribution of birth control information.

Sex Education for Adolescents

No race effect existed regarding the delivery of sex and acquired immunodeficiency syndrome (AIDS) education to teenagers through the public schools (Table 2). Almost all respondents believed that sex and AIDS education should begin before high school, with about 50% indicating that instruction should begin in middle school (i.e., grades 6 to 8). Only 60% of either race believed that sex education was likely to decrease the number of teenage pregnancies.

Adolescent Sexual Activity

Black respondents held significantly more conservative beliefs toward teenage sexual experimentation than did White respondents (Table 3). Approximately 20% of Black adults agreed that it was acceptable for male or female teenagers to engage in premarital sexual intercourse, in comparison with more than 40% of White adults. Two thirds of Blacks and almost 60% of Whites believed that they, personally, should have been better prepared about sex when they were teenagers.

TABLE 1—Community Attitudes toward the Provision of Health Services in Public Schools and Types of Services to Be Provided

	Black (n = 200), %	White (n = 601), %	*P*
Provision of health services			
Health services should be provided at junior high (middle) school	97.0	94.8	.21

Drug and alcohol education	95.4	98.3	.02
Instruction on child care	90.8	84.0	.03

Note. For indexes, means rather than percentages are presented.

Black respondents were also more conservative regarding abortion, being about half as likely as Whites to agree that abortion should be allowed (Table 4). Blacks were less likely to believe that any specific circumstance, such as age of the mother, warranted abortion; the higher Support for Abortion Index score for Blacks reflects this more negative view. After adjustment for sociodemographic characteristics, political orientation, and religiosity, Blacks remained significantly less favorable toward abortion in general and when the pregnancy was due to rape, although no race effect was found for the Support for Abortion Index. Blacks were three times as likely (13.5% vs 4.3%) and about six times as likely (25.5% vs 4.3%) as Whites to believe that an unmarried teenager should either marry the father or keep the baby, respectively.

Discussion

This study is the first description of racial variations in *rural* adults' attitudes regarding adolescent health and sexuality issues. Our findings suggest that Blacks in this rural community are more likely than Whites to support public school–based, comprehensive adolescent health programs. While there was strong support for sex education programs in general, Black adults were more accepting of programs that would also provide general health care and care related to sexuality (e.g., pregnancy testing). We conclude that Black adults of this county are more supportive of adolescent health programs offering a broad spectrum of options, ranging from avoidance of pregnancy through abstinence to school-based day care for infants of teenage mothers. Abortion, however, may be a

APPENDIX—Indexes of Related Questions

Factor analysis was used to identify sets of related questions from which indexes were created. The 24 questions on health services (Table 1) fell into five indexes, of which four had acceptable levels of reliability.

The Preventive Medicine Index consisted of 9 items, including questions about provision of female checkups, physical examinations, and blood tests (Cronbach alpha = .86; mean = 17.4, SD = 5.9).

The Assistance with Personal Problems Index was composed of 6 items focusing on health services such as counseling for eating disorders, instruction on the care of children, and mental health counseling (Cronbach alpha = .72, mean = 7. , SD = 2.5).

The Assistance with Sexual Problems Index was composed of 4 items including distribution of birth control products to girls and boys, counseling for pregnant teenagers, and day care for infants of teenagers (Cronbach alpha = .73; mean = 7.0, SD = 2.7).

The Preventive Education Index consisted of 3 items, including questions about distributing birth control information to girls and boys and provision of drug and alcohol education (Cronbach alpha = .76, mean = 3.3, SD = 1.1).

Because the items presented in Tables 2 and 3 yielded five factors of two questions each, the indexes were no more informative than the individual items and, hence, were not analyzed. The questions on abortion (Table 4) were combined into the Support for Abortion Index (Cronbach alpha = .92, mean = 17.4, SD = 6.1).

The Weights and Heights of Mexican-American Adolescents: The Accuracy of Self-Reports

Harold Davis, MD, and Peter J. Gergen, MD, MPH

ABSTRACT

The accuracy of Mexican-American adolescents' self-reported weights, heights, and body mass indexes was evaluated with data from the Hispanic Health and Nutrition Examination Survey. On average, adolescents with low measured body mass indexes and high measured body mass indexes overestimated and underestimated their weights, respectively. Categories of low and high body mass indexes created by applying cutoffs to reported body mass indexes had low sensitivities. For weight, height, and body mass indexes, measured and reported values were highly correlated. This high correlation suggests that adolescents' reported values can be used as continuous variables in multivariate analyses with only small errors resulting in the coefficients for weight, height, and body mass index. (*Am J Public Health*. 1994;84:459–462)

Introduction

Researchers wanting to collect data on survey participants' weights and heights might find it desirable to obtain such data by self-report. Studies of reported weights and heights usually have focused on adults[1–13]; fewer studies[14–19] have focused on adolescents. To evaluate the accuracy of Mexican-American adolescents' self-reported weights and heights, we used data from the Hispanic Health and Nutrition Examination Survey.

Materials and Methods

Study Design of the Hispanic Health and Nutrition Examination Survey

The Hispanic Health and Nutrition Examination Survey was conducted by the National Center for Health Statistics from 1982 through 1984. The Mexican-American portion was done from July 1982 through December 1983 among civilian, noninstitutionalized persons of Mexican origin or ancestry in Arizona, California, Colorado, New Mexico, and Texas. The sample design was a stratified, multistage probability sample.[20] The weighted estimates presented are representative of Mexican Americans in these states.

The survey included an interview and an examination. For persons who were 12 through 17 years old, either self-response or response by proxy was acceptable. Persons who were 18 years old or older responded for themselves unless they were unable to be interviewed. In the interview, weights (without shoes) were reported in pounds and heights (without shoes) in feet and inches. In the examination (done a few weeks after the interview), weights to the nearest 0.05 kg and heights to the nearest 0.1 cm were measured for participants dressed in light examination clothing without shoes.

Study Population

We used data from the Examination Survey's Mexican-American portion on the Mexican-American males and nonpregnant females who were 12 through 19 years old. Analyses were done on the 392 males and 437 females who self-responded, reported weights and heights,

At the time of the study the authors were with the Division of Health Examination Statistics, National Center for Health Statistics, Centers for Disease Control and Prevention, Hyattsville, Md.

18–19	1.6 ± 0.6	−1.1 ± 0.4	0.5 ± 0.3	0.5 ± 0.2	0.9 ± 0.9	−2.0 ± 0.6

[a]Measured low body mass index group is significantly different from measured high body mass index group.
[b]Males with measured high body mass index are significantly different from females with measured high body mass index.
[c]Underweight group is significantly different from overweight group.
[d]Overweight group is significantly different from about-right-weight group.
[e]Adolescents 12 through 14 years old are significantly different from those 18 and 19 years old.

and had their weights and heights measured.

Statistical Analyses

We used measured values to calculate body mass index as weight/square of height (kilograms/square meter). Based on the 1308 measured body mass indexes of Mexican-American adolescents in the Examination Survey, single year of age-and-sex-specific cutoffs were created (by using sample weights) for three measured body mass index groups: low (≤15th percentile), middle (10th–84th percentile), and high (≥85th percentile). Reported body mass index was calculated by using reported weights and heights and categorized by using these cutoffs.

Sensitivity and specificity of reported low body mass indexes were calculated as (1) sensitivity = 100 × number of adolescents with reported and measured low body mass index/number with measured low body mass index; (2) specificity = 100 × number of adolescents with neither reported nor measured low body mass index/number without measured low body mass index. Analogous methods were used for reported high body mass index.

For each adolescent, a percentage difference between reported and measured values was calculated as 100 × (reported value − measured value)/measured value. The mean percentage difference is the average of these individual percentage differences.

Point estimates were calculated with sample weights. Sampling weights account for selection probabilities and include adjustments for nonresponse and geographic noncoverage. Variances were estimated by multiplying simple-random-sample variance estimates by the average design effect (1.00 in this study).[21] To compare point estimates, *t* tests with 8 *df* were used. To assess trends, linear regression analysis was performed. *P* values of less than .05 were significant.

Results

Self-Reported Weight

The mean percentage difference between reported and measured weights was 0.8% ± 0.4% (SD = 8.5) for males and −1.8% ± 0.3% (SD = 6.7) for females. Weights were reported within ±5% of measured values by 63% of males and 72% of females. For both sexes, adolescents with measured low body mass index on the average overestimated their weights, and those with measured high body mass index underestimated theirs (Table 1).

The correlation coefficient between measured and reported weight was .95 for males and .93 for females and varied little with age group.

Self-Reported Height

The overall mean percentage difference between reported and measured heights was −0.1% ± 0.2% (SD = 3.2) for males and 0.4% ± 0.1% (SD = 2.4) for females. The reported height fell within ±2% of the measured height for 63% of males and 70% of females. Adolescents 12 through 14 years old on the average slightly underestimated their heights, whereas 18- and 19-year-olds slightly overestimated theirs (Table 1).

The correlation coefficient between measured and self-reported height was .86 for males and .86 for females. This coefficient varied little with age group except for males 18 and 19 years old, for whom it was .71.

Self-Reported Body Mass Index

The overall mean percentage difference between the self-reported and measured body mass indexes was 1.3% ± 0.5% (SD = 9.8) for males and −2.4% ± 0.4% (SD = 8.4) for females. On average, reported weights and heights overestimated the body mass index of adolescents with measured low body mass indexes (Table 1). Reported values tended to underestimate the body mass index of adolescents with measured high

TABLE 2—Cross-Tabulation of Self-Reported and Measured Body Mass Index (BMI) Groups, by Sex: Mexican Americans, 12 through 19 Years Old, Hispanic Health and Nutrition Examination Survey, 1982 through 1984

BMI Groups Based on Self-Reported Weight and Height	BMI Groups Based on Measured Weight and Height, %		
	Low	Middle	High
Males			
Low	7.1	4.1	0.2
Middle	7.6	60.7	3.9
High	0.0	3.7	12.8
Females			
Low	10.4	7.2	0.0
Middle	4.2	63.8	5.5
High	0.0	1.0	7.9

Note. Percentages do not add to 100 because of rounding.

TABLE 3—Sensitivity and Specificity of Low Reported and High Reported Body Mass Index (BMI) Groups: Mexican Americans, 12 through 19 Years Old, Hispanic Health and Nutrition Examination Survey, 1982 through 1984

Group	Sensitivity		Specificity	
	%	95% Confidence Interval	%	95% Confidence Interval
Low reported BMI				
Males	48	33, 63	95	92, 98
Females	71	58, 85	92	88, 95
High reported BMI				
Males	76	63, 88	96	93, 98
Females	59	44, 74	99	98, 100

body mass indexes, with greater underestimation for females than males. On average, reported body mass indexes were underestimates to a greater degree for females self-described as overweight than for those described as underweight or about the right weight.

The correlation coefficient between measured and reported body mass indexes was .87 for males and .85 for females and varied little with age group.

The distribution of reported vs measured body mass index groups is shown in Table 2. In neither sex did the sensitivities for reported low and high body mass index reach 80% (Table 3). The specificities for reported low and high body mass index ranged from 92% to 99%. For each sex, there were no significant trends by age group in sensitivity or specificity.

Discussion

We found that categories of reported body mass indexes had low sensitivities. That indicates that cutoffs based on absolute values had a poor ability to correctly classify adolescents. Therefore, using these categories to estimate relative risks associated with categories of body mass index might result in large errors in the estimates, and it is probably best not to use such categories to estimate relative risks.

We found high correlations between reported and measured values for weight, height, and body mass index, indicating that reported values reflect well the relative ranking of measured values. In multivariate analyses with continuous data, using reported values that are highly correlated with measured values is likely to cause relatively small errors in a variable's coefficient.[22] Therefore, using adolescents' reported values in these analyses might result in only small errors in the coefficients for weight, height, and body mass index.

Similarities between this study and most previous studies of reported values in adults and adolescents include a high correlation between reported and measured values[2,4,7,9,10,14,18,19] and a tendency for persons with high body mass indexes to underestimate their weights more than other persons,[2-10,15-18] a tendency that causes a low sensitivity of high body mass index categories formed from reported values.[7,10,13] These similarities suggest that the limitations and possible uses of reported values of Mexican-American adolescents described here will apply to most other adolescent populations. □

The Prevalence of Intrauterine Growth Retardation in Mexican Americans

Hector Balcazar, PhD, MS

ABSTRACT

This study evaluated the prevalence of intrauterine growth retardation in Mexican Americans compared with non-Hispanic Whites in the state of Arizona. Data came from all live birth certificates in 1986 and 1987. Rates of intrauterine growth retardation in Mexican-American and non-Hispanic White infants in Arizona were lower than those in White infants in California. Differences in patterns of the 10th percentile growth distribution curves were observed between infants born in Arizona and those born in California. Compared with non-Hispanic Whites, Mexican Americans had lower adjusted odds ratios for intrauterine growth retardation according to several maternal risk characteristics. (*Am J Public Health.* 1994; 84:462–465)

Introduction

Given the heterogeneity of the Mexican-American population, the study of perinatal health problems should not be confined to low birthweight.[1] In the Mexican-American perinatal population, indicators of fetal growth and maturity at birth have not been used to evaluate intrauterine growth retardation. It is quite likely, therefore, that reported prevalence of low birthweight overlooks a proportion of affected infants. Failure to diagnose intrauterine growth retardation at birth in Mexican-American infants, whether or not they fall into the low-birthweight category, has public health significance.[1,2] Evidence is beginning to accumulate in regard to the detrimental effects on morbidity and mortality in newborns with birthweights above 2500 g.[3–5] This study was designed to evaluate the problem of intrauterine growth retardation in a Mexican-American population.

Methods

All singleton births in Arizona for the years of 1986 and 1987 were evaluated for intrauterine growth retardation. The entry of Spanish origin and race of the mother was used to identify Whites versus Hispanics and those of Mexican origin. The total numbers of single births were 23 799 and 67 280 for Mexican-Americans and Whites, respectively. The percentages of births that occurred out of the hospital infirmary or medical center were 1.9% for Mexican Americans and 2.0% for Whites. Approximately 1.3% of the total birth certificates for each ethnic group were discarded because of missing data on birthweight. Similar percentages of missing data in regard to origin or race of the mother were also found (1% of the total population). For Mexican Americans and Whites, 3.9% and 2.5% of the data, respectively, were missing for the month of the last menstrual period. The prevalence of intrauterine growth retardation was estimated for all infants with birthweight data at 24 to 42 weeks of gestation.

Completed weeks of gestation were computed based on the last normal menses and the date of birth of the infant. If the day of the last normal menses was missing, the 15th day of that month was used. For the purpose of classifying intrauterine growth retardation, the cutoff point of the 10th percentile of each of two different fetal growth distributions was used (Williams et al.[6] and Hoffman et al.[7]). The White (non-Hispanic) population of Arizona was used as a comparison group.

Several maternal risk factors were defined from the certificates of live birth to evaluate the variations in classification of intrauterine growth retardation. Chi-square statistics were used to test for differences in prevalences between groups. Adjusted odds ratios and 95% confidence intervals were calculated to

TABLE 1—Distribution of Newborn Infants, According to Low-Birthweight Classification and Gestational Age, between Mexican Americans and Non-Hispanic Whites

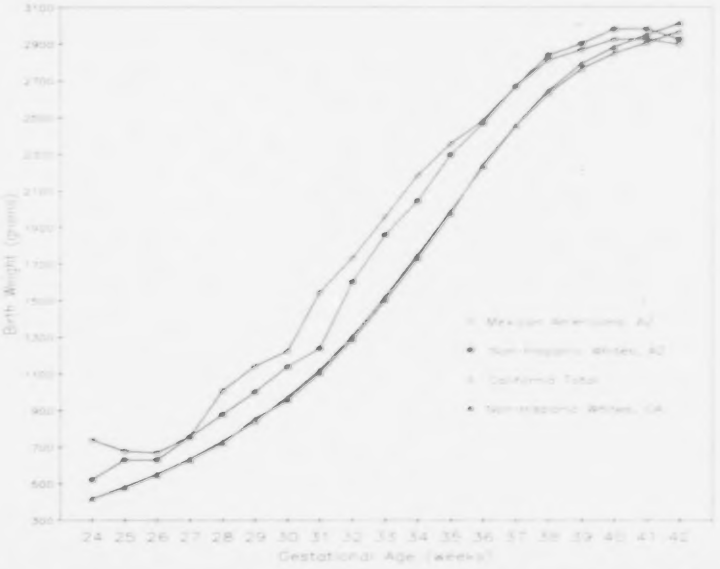
Newborn Classification	Mexican Americans (n = 23 799), %	Whites (n = 67 280), %
< 37 weeks of gestation	14.2	11.1*
< 2500 g	5.1	5.0
< 37 weeks of gestation; < 2500 g	3.1	3.0
≥ 37 weeks of gestation; < 2500 g	2.0	2.0

Note. For the total sample, gestational ages were between 24 and 42 weeks.
*$P < .01$ by chi-square test.

TABLE 2—Prevalence of Intrauterine Growth Retardation in Mexican Americans and Non-Hispanic Whites in Arizona Compared with Two Reference Fetal Growth Distributions

Reference Fetal Growth Distribution	Mexican Americans (n = 23 799), %	Whites (n = 67 280), %	P*
California Non-Hispanic Growth Data[6]	6.3	5.8	.015
National Growth Data[7]	4.9	4.7	.215

Note. Sex-specific cutoff values were used for 10th percentile of each reference growth standard. For the total sample, gestational ages were between 24 and 42 weeks.
*P value for differences in prevalence between Mexican Americans and Whites for the two reference fetal growth distributions according to the chi-square test.



Note. Sample size ranges for Mexican Americans in Arizona are 19–1339 (preterm) and 1219–5296 (term); for non-Hispanic Whites in Arizona they are 50–3244 (preterm) and 3102–16 192 (term). Tenth percentile birthweight values for each gestational age group in the Arizona samples are available from the author on request.
Source. Data for California samples is from Table 2 of Williams et al.[6] and is used with permission from The American College of Obstetricians and Gynecologists.

FIGURE 1—Comparison of 10th percentile cutoff values (birthweight by gestational age) reported for Mexican Americans and Whites in Arizona and California.

evaluate the statistical significance of differences in intrauterine growth retardation between ethnic groups within each level of maternal risk factors. Multivariate logistic regression was used to evaluate differences in intrauterine growth retardation for each maternal risk factor after controlling for the effects of the other maternal characteristics. Data were analyzed on an IBM mainframe computer with the SAS statistical package.[8]

Results

Mexican Americans have a 3.1% excess of preterm delivery compared with Whites (Table 1). Comparable rates of low birthweight are observed for Mexican Americans and Whites. Similar results are also seen for preterm and term low-birthweight groups. The proportions of low birthweight associated with preterm delivery are similar for Mexican Americans and Whites (60.8% vs 60.0%). Among preterm infants, the prevalence of low birthweight differs by ethnic group: 21.6% for Mexican Americans vs 27.2% for Whites ($P < 0.01$).

The prevalence of intrauterine growth retardation for Mexican Americans is 4.9% and 6.3%, respectively, for each of the two reference growth distributions (Table 2). There was a significant difference in prevalence of intrauterine growth retardation between Mexican Americans and Whites (6.3% vs 5.8%, respectively) only with the fetal growth distribution in California.[6] The California reference distribution indicates that more than 60% of the Mexican-American and White infants with intrauterine growth retardation had birthweights greater than or equal to 2500 g. These results are striking considering the fact that 942 Mexican-American and 2398 White infants with intrauterine growth retardation would not have been identified by the low-birthweight criterion alone. Similarly, the two reference growth distributions classify more than 85% of all case subjects with intrauterine growth retardation as term infants in both Mexican Americans and Whites (results not shown).

Figure 1 clearly illustrates the different patterns of birthweight distribution for the 10th percentile cutoff values in

TABLE 3—Intrauterine Growth Retardation[a] among Mexican-American and Non-Hispanic White Infants, by Maternal Risk Characteristics

Maternal Risk Factor	Prevalence of Intrauterine Growth Retardation, %		Adjusted Odds Ratio[c]	95% Confidence Interval

[a]Based on gestational ages between 24 and 42 weeks and the 10th percentile of sex-specific birthweight by gestational age distribution used by Williams et al.[6]
[b]Differences in intrauterine growth retardation within ethnic groups for each variable are all statistically significant ($P < .05$) except for education in Mexican Americans.
[c]The odds ratio was calculated by using the maternal risk characteristic distribution of non-Hispanic Whites. These odds ratios were adjusted for all the other maternal risk characteristics.

Arizona vs California populations of infants. The cutoff birthweight values for the Arizona population (including both Mexican Americans and Whites) are higher than those for the California population for each week of gestational age (excepting the 42nd week). Differences in the distribution of birthweights between Mexican Americans and Whites in Arizona are also noticeable. Note that for the Mexican-American subgroup (as well as for the White sample) the 10th percentile cutoff for term infants exceeds the 2500-g low-birthweight criterion.

Differences in intrauterine growth retardation according to maternal characteristics within each ethnic group are all statistically significant, except for education in Mexican Americans (Table 3). In addition, significantly lower adjusted odds ratios associated with intrauterine growth retardation were found in Mexican Americans compared with Whites for at least one level within each of the maternal characteristics shown in Table 3.

Discussion

This analysis clearly demonstrates that the classification of low birthweight (birthweight less than 2500 g) fails to identify infants with intrauterine growth retardation or those who are small for gestational age. Even though there were differences in intrauterine growth retardation between Mexican Americans and Whites, the rates of intrauterine growth retardation for both groups were considerably lower than the 10% rate expected based on that for non-Hispanic Whites in the California reference growth distribution (10th percentile).

Three major factors that must be acknowledged when exploring the prevalence of intrauterine growth retardation in Mexican Americans are the reference fetal growth distribution used,[9] the evaluation of the effect of measurement error associated with estimation of gestational age,[10,11] and the presence of sampling bias or systematic error in determining birthweight or gestational age.

Differences in prevalences of intrauterine growth retardation between groups are probably related to the higher birthweight values observed for Mexican Americans and Whites in Arizona throughout the range of gestational ages compared with the California data set. Factors that might have shifted the distribution towards higher birthweights in Mexican Americans and Whites in Arizona are related to underestimation of gestational age (particularly for preterm or near-term infants) and the exclusion of a sample of infants because of unknown birthweight, unknown origin or race of the mother, or unknown gestational age. The overall effect of these errors probably resulted in underestimation of the prevalence of intrauterine growth retardation in both Mexican Americans and Whites in Arizona. However, it is possible that this phenomenon of higher birthweights observed in Arizona vs California infants is real, rather than artificial.[12]

The large share of intrauterine growth retardation accounted for by term and non–low birthweight infants could have been partially accounted for by measurement error in gestational age estimation. Kramer et al.[13] presented evidence that overestimation of gestational age in postterm gestations due to either delayed ovulation or missed spontaneous abortions may play an important role in explaining systematic errors in measurement of gestational age. In this regard the crossover effect of birthweight observed between the populations of Arizona and California shown in Figure 1 (at 42 weeks of gestation) needs to be carefully examined. Note that the same crossover effect is also observed between Mexican Americans and Whites in Arizona (Figure 1). This effect has also been shown in California.[12] Problems associated with differential underreporting of very small and preterm infants, as suggested by ethnic differences found in preterm infants weighing less than 2500 g (Table 1), need to be examined also.

The rates of intrauterine growth retardation in Mexican Americans described here suggest the need to evaluate the appropriate reference growth distribution to be used for the population of Mexican-American infants in Arizona. Thus, population based–clinical studies are needed to explore this issue (including the evaluation of morbid-

ity and mortality outcomes according to ethnicity and socioeconomic status). In this regard, the use of a criterion less restrictive than the 10th percentile should also be tested when evaluating intrauterine growth retardation in these groups (i.e., the use of standard or percentage deviations from mean birthweight throughout all gestational ages).[14–17] Finally, information on maternal determinants of intrauterine growth retardation between groups was not available for investigation in order to confirm the results of the risk ratios presented. □

DHHS Minority Health Resource Center Established

The US Department of Health and Human Services, Office of Minority Health, has established a resource center to provide health professionals with resources and referrals on minority health. The Office of Minority Health Resource Center operates a toll-free telephone number for inquiries on the health status of Asian, Black, Hispanic, Native American, and Pacific Islander populations.

The center's services and products include the following:

- **The center conducts database searches for documents on minority health, national organizations, and community-based programs.**
- **It supplies copies of research articles and other relevant materials on more than 100 subjects.**
- **It provides technical assistance.**
- **It links users with experts nationwide for conferences and program efforts.**
- **It refers users to data resources.**
- **It provides minority media resources.**
- **It distributes a newsletter, resource lists, grantsmanship materials, and federal health promotion/disease prevention books.**

These services and products are offered free of charge, and the library is accessible to visitors. To obtain information or schedule an appointment, write or call the Office of Minority Health Resource Center, PO Box 37337, Washington, DC 20013-7337; tel 1-800-444-6472.

The Proportion of Veterans among Homeless Men

Robert Rosenheck, MD, Linda Frisman, PhD, and An-Me Chung, PhD

ABSTRACT

This study used data from four surveys conducted in 1986/87 to identify age–race cohorts of homeless men in which veterans are overrepresented. The overall proportion of veterans among homeless men (41%) was somewhat higher than that in the general population (34%). This overrepresentation is largely attributable to the disproportionate representation of veterans in the youngest age cohort (20 to 34 years) of homeless White men. Veterans in this group are 4.76 times more likely to be homeless than nonveterans. Other national data on this cohort reveal higher rates of unemployment, substance abuse, and antisocial personality among veterans than among nonveterans. (*Am J Public Health.* 1994; 84:466–469)

Introduction

Community surveys conducted during the 1980s reported that, on average, 38% of homeless men were veterans (range = 29% to 49%),[1–7] as compared with only 30% of men in the general population.[8] While these findings suggest that veterans may be at a somewhat greater than expected risk for homelessness, such an overrepresentation is not easy to explain. Most veterans are entitled to special benefits, including educational assistance, home loan guarantees, pension and disability payments, and free health care. In 1990, veterans had higher median incomes, had lower rates of poverty and unemployment, and were better educated than nonveteran US men in similar age groups.[9] These data suggest that veterans should be *less* vulnerable to homelessness than other Americans. The present study sought to determine whether veterans, in general, are disproportionately represented among homeless people or whether vulnerability to homelessness is specific to one or another age or race cohort of veterans.

Methods

Estimates of Proportions

The proportion of male veterans among homeless men was estimated through secondary analyses of the Urban Institute's 1987 national survey of homeless service users (n = 1140)[10] and three single-city surveys conducted in Los Angeles (n = 270),[11] Baltimore (n = 295),[12] and Chicago (n = 486)[13] between 1985 and 1987. These studies were chosen because of their sophisticated sampling strategies (see the original publications for details) and overall rigorous design. Veteran status, judged in all four studies from a single question concerning past US military service, was used to estimate the proportion of veterans among homeless men within each of five age cohorts (20 through 34, 35 through 44, 45 through 54, 55 through 64, >64) and by race (White vs Black).

The 1987 Current Population Survey, a national household survey conducted by the Bureau of the Census, was used to estimate the proportion of male veterans in the general population in each of these age–race cohorts.[14] These data were used to estimate odds ratios (ORs) of homelessness among veterans as compared with nonveteran US men.

Adjustment Factors Associated with Veteran Status

To account for differences in the risk of homelessness among veterans relative to nonveterans in the various age–race cohorts, we also compared veterans and nonveterans in the general population on factors that have been associated with homelessness.

Socioeconomic characteristics. Further analyses of the Current Population Survey were undertaken to compare veterans and nonveterans on personal income, poverty rates, unemployment, educational achievement, marital status, and household size.[14] Only the subgroup of men whose income was less than twice the poverty level were included in the last four analyses.

Psychiatric and substance abuse disorders. An analysis of the public access data tape of the Epidemiological Catchment Area Study was conducted to compare rates of lifetime psychiatric and substance abuse diagnoses among male veterans and nonveterans in each 1987 age–race cohort.[15]

Military service. Information regarding service era and combat exposure of veterans in various age groups was obtained through analyses of data from the Third Survey of Veterans, a 1987 survey of a representative national

This paper was accepted July 13, 1993.

sample of 9442 noninstitutionalized veterans.[16] These analyses were also limited to low-income veterans: those who earned less than $15 000 per year (the bottom third of the veteran income distribution).

Results

Veterans among Homeless Americans

Results were similar from all four homeless surveys, and unweighted data were combined to simplify their presentation. Among homeless men more than 20 years old, 41% reported past military service, as compared with only 34% in the general population of US men surveyed in the 1987 Current Population Survey (Table 1).

Odds ratios (Table 2) show significantly greater likelihood of homelessness among veterans 20 to 34 and 45 to 54 years of age than among nonveterans in the general population. The most dramatic finding is that White veterans 20 to 34 years old were 4.8 times more likely to be homeless than their nonveteran counterparts in the general population (95% confidence interval [CI] = 3.8, 5.9). Although the risk of homelessness was also elevated among Black veterans in this age group, the odds ratio (2.1, 95% CI = 1.7, 2.7) was significantly lower than that for Whites. Homelessness was also increased among veterans 45 to 54 years old (OR = 1.7, 95% CI = 1.4, 2.1), but differences between races were not significant.

Note. OR = odds ratio; CI = confidence interval.
[a]Includes Whites, Blacks, and others.

Socioeconomic Factors

Data from the 1987 Current Population Survey show that the average personal income among White veterans 20 to 34 years of age was about the same as that of White nonveterans ($17 490 vs $17 653), as were poverty rates (10.0% vs 10.8%). White veterans aged 20 to 34 were more likely to be unemployed than nonveterans (18.6% vs 11.4%), but veterans of all ages and races, including White veterans aged 20 to 34, were more likely to have a high school degree, more likely to be married, and no more likely to be living alone than their nonveteran counterparts (data available on request).

Psychiatric Risk Factors

Among White men in the 20- to 34-year-old cohort, prevalences of non–substance abuse psychiatric disorders and substance abuse disorders were two to three times higher among veterans than among nonveterans, and rates of antisocial personality disorder were five to six times as high (Table 3). In contrast, Black veterans in this age cohort, in comparison with Black nonveterans, showed a significantly greater prevalence for lifetime substance abuse disorder only. Other veteran age–race groups, for the most part, showed no greater rates of these disorders than nonveterans.

Military Service Characteristics

Data from the Third Survey of Veterans revealed that veterans in the 20 to 34 and 45 to 54 cohorts were far less likely than other veterans to have served during a wartime service era or to have been exposed to combat (data available on request). Among the 20 to 34 age group, 79% served during the post-Vietnam era (the era of the All Volunteer Force), and only 7% served in combat. Among the 45 to 54 age group, 78% served between the Korean and Vietnam eras, and only 17% served in combat. More than 40% of veterans in other age groups, in contrast, reported combat service.

Discussion

The proportion of veterans among homeless male Americans is greater than the proportion in the general population, but this overrepresentation is most striking among Whites 20 to 34 years old; to a lesser extent, Blacks 20 to

*$P < .10$, **$P < .05$; ***$P < .001$.

34 years of age and 45- to 54-year-old men of both races are overrepresented. Although Current Population Survey data are national rather than strictly urban, as in the case of the survey data, they suggest no special socioeconomic vulnerabilities among high-risk age–race cohorts of veterans. The much higher prevalence of psychiatric illness, substance abuse, and, especially, antisocial personality disorder among White veterans 20 to 34 years old would seem to be a likely contributor to the greater vulnerability to homelessness of this group. Veterans in these most vulnerable groups are the least likely to have served during wartime or in combat, reducing the role that can be attributed to combat stress in the genesis of homelessness among veterans.

Perhaps the most distinctive characteristic of veterans in the vulnerable age cohorts is that they served during nonwartime eras, especially during the post-Vietnam era, after establishment of the All Volunteer Force in 1973. The shift to the volunteer force marked an important change in military manpower policy, a change that was accompanied by widespread concern that the military would become an employer of last resort for poorly skilled youth.[17,18] Studies comparing volunteer force recruits and age-matched civilians show these recruits to have had slightly lower socioeconomic status than their nonveteran peers,[19–21] as well as poorer intellectual aptitude test results[22,23] and greater problems with substance abuse.[24–26]

Although it appears that, during the post-Vietnam era, young adults with greater psychopathology and lower earning potential joined the military, this does not appear to have been the case during the period between Korea and Vietnam.[17] Nonwartime era veterans, however, are eligible for a more limited range of Veterans Affairs benefits. Only 25% of post–Korean era veterans used GI Bill educational benefits, as compared with 54% of Vietnam era veterans.[16] More limited availability of Veterans Affairs benefits may therefore have played some role in increasing the risk of homelessness among veterans in the 45 to 54 age cohort.

Since veteran status in this study was not validated through a review of military records, it is possible that, either as a point of pride or in the hope of obtaining some other advantage, some homeless respondents may have falsely claimed military service, thus inflating estimates of the number of veterans among homeless people. This seems unlikely, however, since there is no reason to expect such falsification in some age–race cohorts more than in others.

Since the homeless surveys involved prevalence rather than incidence samples, an association between veteran status and duration of homelessness could have biased our results.[27] Other studies, however, suggest no difference between veterans and nonveterans in duration of homelessness.[28]

Veterans appear to be overrepresented among homeless men, but this overrepresentation primarily affects younger veterans who served in nonwartime eras, especially the post-Vietnam era. The increased vulnerability for homelessness among veterans may be related to the admission of poorly adjusted young men to military service during nonwartime eras and to the reduced availability of Veterans Affairs benefits to these veterans. □

The Driver's License List as a Population-Based Sampling Frame in Iowa

Charles F. Lynch, MD, PhD, Nyla Logsden-Sackett, MS, Sandra L. Edwards, MA, and Kenneth P. Cantor, PhD, MPH

ABSTRACT

Driver's license lists are infrequently used for population-based sampling, presumably because of suspicions of poor population coverage. The 1990 Iowa driver's license list was compared with the 1990 census to evaluate coverage by 5-year age group, sex, resident county, and urbanicity. Coverage exceeded 90% among 15- to 74-year-old men and 15- to 64-year-old women, with uniform coverage by county and county urbanicity group in these age ranges. In Iowa, these lists are convenient and cost-effective and appear to be representative for 25- to 64-year-olds. The representativeness of driver lists in regard to other factors and in other geographic regions deserves further evaluation. (*Am J Public Health.* 1994;84:469–472)

Introduction

Epidemiology is among many research disciplines that struggle with subject selection for population-based studies. Complete population rosters are rarely available. Without such listings, researchers must identify sampling frames that adequately represent the target population.

In the United States, sampling frames can be compared with the decennial census, stratifying on a few factors that serve as indicators of overall representativeness. We applied this strategy to examine the adequacy of driver's license lists as a sampling frame. We identified age groups with high coverage and then stratified by sex, county, and four levels of county urbanicity to assess representativeness within these groups.

Methods

The Iowa Department of Transportation provided driver's license data in February 1991. We adjusted this data set to reflect resident license holders on April 1, 1990, and then compared it with 1990 census enumerations.[1] Approximately 5% of these records were for nondrivers with picture identification cards.[1]

The original data set contained 2 506 843 records. We eliminated (1) 18 records involving birth dates before January 1, 1870, or after April 1, 1990; (2) 1836 records listing a state of address outside Iowa; (3) 279 records listing nonexistent county codes; (4) 3081 duplicate records; (5) 2313 deceased individuals; (6) 121 887 individuals who had

[a]Excludes individuals who died or surrendered their Iowa license for an out-of-state license on or before April 1, 1990, or whose license was expired as of April 1, 1990, and not renewed as of March 1, 1991.
[b]Driver's license count/census count.

surrendered their Iowa licenses by April 1, 1990; and (7) 204 288 individuals whose licenses had expired by April 1, 1990, and were not renewed by March 1, 1991. A total of 333 530 records were dropped from the original data set after meeting one or more of these exclusion criteria, leaving 2 173 313 records.

We stratified the 99 Iowa counties into four mutually exclusive urbanicity groups: (1) 11 counties containing at least one census-defined metropolitan area, (2) 37 counties with no metropolitan areas, but with at least 40% of the population residing in census-defined urban areas, (3) 31 counties with no metropolitan areas and with less than 40% of the population residing in urban areas, and (4) 20 rural counties.

Results

Table 1 compares the adjusted 1990 Iowa driver's license list with the Iowa portion of the 1990 census by 5-year age group and sex. The 0- to 9-year-olds listed have picture identification cards, not driver's licenses. Coverage exceeding 90% is observed among 15- to 74-year-old males and among 15- to 64-year-old females. Overall, coverage decreases gradually with age. In every age group, coverage of males is slightly higher than that of females.

Table 2 shows no substantial differences between county groups except in the 15- to 24-year age range. In this age group, overcounts are observed in the low urbanicity and rural county categories.

Table 3 provides the numbers of individuals who surrendered their Iowa license for a license in another state. Most out-migration occurred among 20- to 29-year-olds.

County-by-county ratios of driver counts to census counts for 25- to 64-year-old men ranged from 0.87 to 1.15. For 25- to 64-year-old women, ratios ranged from 0.90 to 1.08. No regional patterns were evident for either sex.

Discussion

Our results suggest that Iowa driver's license lists adequately represent 25- to 64-year-old residents. Among 15- to 24-year-olds, coverage was high but was related to urbanicity of resident county. Our coverage estimates for 25- to 54-year-olds must be interpreted with caution because we were unable to adjust for driver overestimates (Table 1). Table 3 shows that out-migration occurs most frequently in this same age group, suggesting that out-migration largely accounts for the overestimates. Among 55- to 64-year-olds, out-migration is infrequent, suggesting that coverage estimates are accurate for this age group. We would expect these coverage estimates (above 90%) to be similar among other preretirement age groups (25- to 54-year-olds).

Our conclusions confirm the findings of a 1970s Kentucky study involving stratified sampling on age and sex; in that study, driver lists provided "an excellent" sampling frame for all adult age groups.[2] In addition, the US Department of Transportation compared 1989 Bureau of the Census estimates with 1990 driver's license holders.[3] Of the adult population nationwide, 94.7% of men and 82.8% of women had driver's licenses. Coverage surpassed 90% for men between 20 and 69 years of age and for women between 30 and 49 years old.

Our conclusions also support findings in a recent cancer case–control study[4] in which we selected 40- to 64-year-old controls from Iowa driver's license records. Among 40- to 64-year-old tumor registry patients, 97% of men and 92% of women reported holding driver's licenses. Therefore, selecting controls from driver's records was unlikely to have introduced any substantial selection bias.

The lists were extremely convenient and cost-effective to use. To obtain subject telephone numbers, we used telephone directories, directory assistance, and, for unlisted numbers, a memo to the respondent requesting the telephone number. We successfully contacted 95.8% of the 1077 originally selected driver's license control subjects by these means. We encountered one disadvantage: Iowa license records are updated for address changes only at the 4-year license renewal. This resulted in increased effort in locating some individuals. Limiting the sampling frame to recent license issues was not an effective solution because renewals occur in age cycles, introducing an age bias.

Other population-based sampling frames have provided poor coverage and/or poor representation in some research settings. These include motor vehicle registries,[2] telephone directories,[5–10] county assessors' lists of property owners,[11] commercial city directo-

Note. The driver's license category excludes individuals who died or surrendered their Iowa license for an out-of-state license on or before April 1, 1990, or whose license had expired as of April 1, 1990, and was not renewed as of March 1991. Metropolitan area counties contain at least one community of 50 000 or more people; nonmetropolitan, high urbanicity counties do not contain metropolitan areas, but more than 40% of the county population lives in urban areas (2500 or more people); nonmetropolitan low urbanicity counties have less than 40% of the county population in urban areas; rural counties contain no metropolitan or urban areas.

[a]Driver's license count/census count.

ries, and voter registries.[2,11] Health Care Financing Administration lists have high coverage nationwide,[12–14] but only for those 65 years of age and older.

Even the frequently used random-digit dialing method[15] underrepresents segments of the population in some locations.[8,16–18] In addition, random-digit dialing involves a large amount of wasted effort calling unassigned and nonresidential numbers.[19–21] Attempts to reduce expense may bias the sample.[22] Furthermore, random-digit dialing usually requires household screening, increasing costs and often reducing response rates.[23]

We believe that driver's license lists are superior to many of these commonly used population-based sampling frames for Iowa. They are available for a nominal fee, computerized, and pooled statewide. New license issues are added promptly. Variables commonly used as eligibility criteria (birth date, sex, address, residence city, and residence county) are contained in license records. Therefore, household screening to select subjects is usually unnecessary, significantly reducing expense and increasing response rates. The vision, literacy, and health requirements for driving may

Neural Tube Defects in Jamaica following Hurricane Gilbert

E. Marilyn Watson Duff, MScNutr, BScN, and Edward S. Cooper, MB, BS, FRCP

ABSTRACT

An increased incidence of obvious live-birth neural tube defects (i.e., spina bifida cystica and encephalocele) occurred in Jamaica 11 to 18 months after Hurricane Gilbert. The conceptions of the affected babies coincided with a rise in megaloblastic change in sickle cell patients, suggesting a widespread drop in dietary folate intake. A detailed history was taken from each of the 17 affected mothers (case subjects) and 51 unaffected mothers (matched control subjects). The case subjects reported a significantly lower mean intake of dietary folate in the periconceptional period (154 μg/day) than did the control subjects (254 μg/day). The temporary increase in neural tube defects was associated with a diet comparatively low in folate in the periconceptional period, suggesting the dietary level of folate that fails to protect against neural tube defects under natural conditions. (*Am J Public Health.* 1994;84: 473–476)

Introduction

In 1991 the Medical Research Council Vitamin Study showed that recurrence of neural tube defects could be prevented by daily supplementation of the diets of high-risk mothers with 4 mg of folate around the time of conception.[1]

After the publication of this report, there was controversy over the dosage of folate supplementation and particularly the possible toxic effects of circulating unmetabolized free folate on the developing embryo.[2–6] In addition, differences of opinion existed worldwide as to what may be considered a folate-replete diet.[6–9]

In Jamaica, the incidence of obvious live-birth neural tube defects (spina bifida cystica and encephalocele) is low, averaging 1.4 per 10 000 live births over 10 years (an average of 2.0 referrals per quarter). In the aftermath of Hurricane Gilbert (September 12, 1988) there was an increase in live-birth neural tube defects with a peak of 5.0 per 10 000 (7 referrals) in one quarter. This increase, which has been reported elsewhere,[10] was significant (Poisson model; $P < .005$) and coincided in periconceptional time with an overt, significant increase in folic acid deficiency in a vulnerable group: homozygous sickle cell patients.[11]

The overwhelming, all-island devastation in the aftermath of Hurricane Gilbert greatly enhanced recall of events around that time. The results presented here, despite the retrospective nature of the information and the small numbers, shed light on the dosage controversy and the range of daily dietary folate that is inadequate to prevent neural tube defects.

Methods

The cases were the 17 mothers of babies with obvious live-birth neural tube defects (spina bifida cystica and encephalocele) born in the third and fourth quarters of 1989 and the first quarter of 1990 who were referred for treatment within the Jamaican hospital system. All cases of neural tube defects were clinically confirmed in tertiary institutions. Anencephaly was excluded because such cases are not usually referred and reports of this diagnosis could not be confirmed. No record of an anencephalic live birth or stillbirth was available from the main hospitals nor from the Ministry of Health. The recording of such birth defects is known to be deficient.[12]

Each case subject was matched with three control subjects, mothers of babies with a birthweight of >2.5 kg and without any apparent physical or developmental defects. Case and control subjects were matched for maternal age, month and year of conception, periconceptional geographic location (Figure 1), parity, and educational level. All of the subjects were of similar socioeconomic and ethnic background (African descent).

A 56-item questionnaire was used in a structured personal interview of each of the case and control subjects by the sole investigator (E.M.W.D.). Blinding of the identities of the case and control subjects was not feasible. Each interview was completed within 11–18 months of the subject baby's birth. The questionnaire was developed, pretested, and precoded to explore 32 health, environmental, and dietary variables in the postdisaster periconceptional period of each subject's pregnancy (see Appendix). Question 55 consisted of a "food folate content scale" that listed 34 common food items and their estimated folate content, designed to give an approximate indication of the subject's daily intake of free folate (in micrograms) in that period for comparison between case and control subjects. This scale was developed from food composition tables[13] and prorated for local dietary servings.

TABLE 1—Mean Daily Folate Intake Reported in the Periconceptional (Post-Hurricane) Periods of Neural Tube Defect Case Subjects and Control Subjects

Group	No.	Mean ± SD Daily Folate Intake (μg)	95% CI
Case subjects	17	153.6 ± 49.3	123, 185
Control subjects	50[a]	253.9 ± 64.3	233, 275

Note. $t = -5.86$; $df = 65$; $P < .0001$.
[a]One high outlying score was omitted from analysis.

The periconceptional period was defined as an 18-week period starting 12 weeks before conception and ending 6 weeks after conception.

Information on postdisaster food availability and relief supplies was obtained from the Salvation Army, the main relief agency.

The mean folate scores of group 1 (case subjects) and group 2 (control subjects) were compared by using the *t* test for independent samples. Fisher's Exact Test and the corrected chi-square test were also used where applicable. Possible confounding variables such as minor trauma and oral contraceptive use were controlled for with multiple logistic regression analysis.

Results

The mean daily dietary intake of folate was significantly lower ($P < .0001$) in group 1 (case subjects) (154 μg/day, 95% confidence interval [CI] = 123, 185) than in group 2 (control subjects) (254 μg/day, 95% CI = 233, 275) (Table 1, Figure 2). The range for group 1 was 60–220 μg/day. The range for group 2 was 140–410 μg/day with a high outlying intake of 616 μg/day, that of the only mother (control subject) who in addition to a dietary intake of 445 μg/day supplemented herself with a multivitamin "liquid food" preparation containing folic acid (approximately 170 μg/day). For each case subject the mean folate intake of the matched control subjects was higher (Figure 3).

There was no association with maternal smoking; alcohol, marijuana, or other substance abuse; pesticide exposure; intake of previously suspected teratogenic foods (i.e., ackee,[14] potato,[15] cassava, Jamaican white yam[16]); bush teas; pica; sources of drinking water; clinic attendance; environmental or psychosocial stress; hyperemesis; hypertension; spacing of pregnancies; incestuous parenting; or previous birth defects.

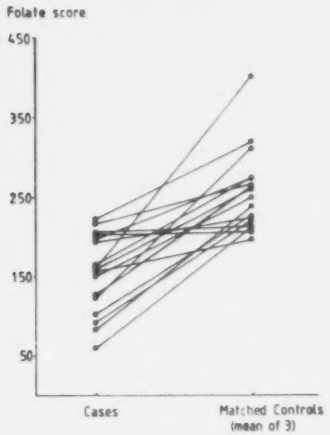
There was no apparent relationship with maternal medication use, but oral contraceptive use[17] was higher among the case subjects, and this difference approached statistical significance (odds ratio [OR] = 3.8, 95% CI = 0.95, 15.44, $P = .058$).

No previous birth defects were reported by any of the subjects in either group. Stillbirths were reported to have occurred in previous pregnancies of two of the case subjects and none of the control subjects. Trauma (minor trauma from blows and falls) was reported only by subjects in group 1 (OR = 5.3, 95% CI = 3.16, 8.73, $P < .0005$). There was no apparent explanation for this.

Population fertility (live births) increased by 4.3% over the same months of the previous year (Statistical Institute of Jamaica, 1988–1990, unpublished data). Although there was no general shortage of food reported by the subjects, there was a change in eating patterns at that time, towards the use of prepared and packaged foods (relief supplies consisting of rice, flour, sugar, cornmeal, tinned corned beef, sausages, sardines, and mackerel) with a considerably reduced intake of fresh produce.

Discussion

We recognize the limitations of retrospective data and a study in which blinding of case and control identities was not practicable, but the special opportunity presented by this experiment of nature mandated the investigation.



Note. In each instance the mean folate intake of the three matched control subjects was higher than that of the case subject.

FIGURE 3—The dietary folate intake scores (micrograms/day) of each case subject compared with the mean dietary folate intake scores of the three matched control subjects.

Within these limitations, the results show that this post-Hurricane Gilbert increase in neural tube defects was associated with a diet comparatively low in folate in the periconceptional period.

The range of reported daily dietary folate intakes among the case subjects (60–220 μg/day) and among the control subjects (140–410 μg/day) gives an approximate indication of the folate content (i.e., micrograms of free folate daily) of the individual diets of the mothers in their post-hurricane periconceptional periods. From this result it may be suggested that a dietary intake of <220 μg of folate per day in the periconceptional period may be inadequate to prevent neural tube defects in the babies of Jamaican mothers. No estimate of the converse, the intake that is protective, can come from a case–control study such as this one.

The MRC Vitamin Study Research Group suggested that the United Kingdom may have a lower folic acid intake than other countries.[1] The usual daily mean intake of folate for British women is 209 μg/day.[8]

The U.S. recommended daily allowance for folate is 180 μg/day for nonpregnant women and 400 μg/day during pregnancy. In the 1976–1980 US Health and Nutrition Survey, median folate intakes were 166 μg/day and 146 μg/day for White and Black women, respectively.[6]

Scott et al.[8] and Leeming[4] emphasized the danger of exposure of the developing embryo to circulating unmetabolized folic acid arising from high-dose supplementation. They recommend that a woman contemplating pregnancy could avoid neural tube defects in her baby by either taking a low-level folic acid preparation or eating an improved or even fortified diet high in folic acid. Strieff[18] suggested that orange juice was a good dietary supplement for folic acid. This suggestion was endorsed by Lucock et al.,[3] who demonstrated in their experiments an enhanced absorption and metabolism of folic acid after ingestion of 500 mL of pure orange juice.

In view of possible adverse reactions to high-dose folic acid supplementation and the recognized interrelation of nutrients in a varied diet adequate in folic acid and related nutrients (such as ascorbate, pyridoxine, and cobalamin), it has been suggested that dietary sources of folate may be preferable to high-dose supplementation.[7]

The Jamaican diet usually includes a wide variety of tropical fruits and vegetables throughout the year. Many of these (e.g., ripe bananas and oranges) contain appreciable amounts of folate and ascorbate. Chicken and beef liver and kidney, eggs, callaloo (a local vegetable similar to spinach), avocados, and steamed rice are also popular in the Jamaican diet. That may account for the usually low incidence of neural tube defects in the Jamaican population.

The massive destruction of crops and livestock wrought by Hurricane Gilbert had immediate impact on the diets of the people of Jamaica. Fresh produce was scarce and therefore expensive.[11] Many of the mothers reported returning to their usual diets 3 to 4 months after the hurricane. □

APPENDIX—List of Variables Investigated by the Structured Personal Interview

1. *Personal information.* Subject's name, address, age, and educational level; occupations of subject and spouse; socioeconomic status (by employment skills rating); family structure; smoking; medication; substance use and abuse.
2. *Antenatal care.* Parity, previous stillbirths and/or birth defects, contraceptive use, spacing, general health, illnesses, accidents, results of diagnostic tests, medication, supplements, clinic attendance.
3. *Index baby.* Name; sex; date of birth; gestation; birth weight; month, year, and place of conception; place and type of delivery; health status at birth; admission(s) to hospital, diagnosis, treatment, and outcome.
4. *Hurricane experiences.* Subject's personal experiences in the aftermath of Hurricane Gilbert. Physical and psychosocial stress, damage, relocation, available food, drinking water.
5. *Periconceptional period.* Nutritional status (as described by the subject), supplements, medications, oral contraceptive use, illnesses, accidents, smoking, substance use and abuse, use of "bush teas," exposure to pesticides, consumption of previously suspected teratogenic foods (i.e., potato, Jamaican white yam, ackee, and/or cassava), pica, unusual stressful events. Exploration of periconceptional diet, determination of the "folate score."

The Use of Commercial Tanning Facilities by Suburban Minnesota Adolescents

Jennifer A. Oliphant, MPH, Jean L. Forster, PhD, MPH, and Colleen M. McBride, PhD

ABSTRACT

In 1991, 1008 suburban St. Paul, Minn, high school students were surveyed via self-administered questionnaire regarding use of commercial tanning facilities, injuries experienced from tanning, use of protective measures while tanning indoors, and knowledge of the risks of tanning. Overall, 34% of the respondents had used commercial tanning facilities. Fifty percent said they had not been warned by tanning facility operators about the risks of tanning indoors, 28% reported not being told to wear goggles, and 17% reported never wearing goggles. The results indicate that these adolescents use commercial tanning services at high rates, and often in ways that increase their risk for a variety of health problems. (*Am J Public Health*. 1994;84:476–478)

Introduction

Exposure to ultraviolet radiation, such as that from artificial tanning devices, is a risk factor for a variety of health problems including erythema, vesiculation, photosensitizing reactions, actinic elastosis, keratoses, basal cell and/or squamous cell carcinoma, and malignant melanoma.[1–3] Exposure to ultraviolet radiation can also result in compromised immune response, eye burns, and cataracts.

The risk of many health problems is higher when ultraviolet radiation exposure occurs prior to adulthood.[4] The damage begins with a child's first exposure and accumulates through his or her lifetime.[5,6] It is estimated that up to 78% of the risk from ultraviolet radiation exposure is completed by age 18.[7]

Indoor tanning is not safer than tanning in natural sunlight. Commercial tanning devices emit either mostly ultraviolet A or mostly ultraviolet B.[2,8,9] Although ultraviolet B injures the skin faster, ultraviolet A penetrates the skin more deeply.[9,10] Some commercial tanning beds may emit as much as 10 times more ultraviolet A than natural sunlight.[2]

Artificial tanning produces no known health benefits,[3] nor is it thought possible to tan safely.[6] Exposure to ultraviolet radiation from indoor tanning increases the chances of developing cancer from natural sunlight.[11,12] The sun protection factor from tanning indoors is only about 4, which offers no significant protection from sun exposure.[13] Moreover, severe ultraviolet radiation burns (those that cause pain for 48 hours or more[14]) increase the risk for malignant melanoma.[4,15]

Despite the serious risks associated with artificial tanning, fewer than half of the states currently regulate commercial tanning facilities. The US Food and Drug Administration (FDA) regulation requires only that the device be equipped with a calibrated timer, protective eyewear, and a small warning label.[16] A previous study found that 45% of all commercial tanning devices examined

did not have the mandated FDA warning label and 50% of the commercial facilities surveyed had at least one improperly labeled machine.[17]

Despite the risks of artificial tanning, little information is available concerning use of tanning devices among the general population and specifically among adolescents. The purpose of this study was to characterize for the first time the prevalence and patterns of use of indoor tanning facilities by adolescents, the health problems associated with adolescents' use of commercial tanning equipment, and adolescents' knowledge of the risks associated with indoor tanning.

Methods

The study sample consisted of all students in grades 9 through 12 from a suburban high school in the St. Paul, Minn, metropolitan area. The survey was self-administered during homeroom and took approximately 5 minutes to complete. A copy of the instrument is available from the author on request. The response rate was 84% (13% absent or missing, 2% refusing, and 1% insincere reporting), yielding a final n of 1008. The sample resembled the Twin Cities suburban population; 88% of the respondents were White. Females slightly outnumbered males (51% to 48%). Participants' ages ranged from 13 to 19 years.

In the survey, students were asked questions to determine their skin type, their history of sun exposure, and their current and past use of commercial tanning equipment. In addition, they were asked to report problems experienced as a result of tanning indoors, their use of protective eyewear, and information received from tanning facility operators regarding the risks of indoor tanning. Questions to ascertain the students' knowledge about the risks of tanning indoors were also asked.

Chi-square tests for independence were used to determine whether high-risk tanning behaviors were associated with each other.

Results

Overall, 34% of the students reported using a tanning facility (Table 1). The lifetime prevalence of indoor tanning was 51% for females and 15% for males. Almost 20% of those aged 14 years or younger reported using a tanning facility; those aged 15, 16, and 17 years or older reported 29%, 34%, and 46% use, respectively. Students' age of first indoor tanning ranged from 9 to 18 years, with more than half beginning before age 15 (Table 2). Those who reported at least one exposure to indoor tanning (n = 331) will be referred to as "tanners."

Most tanners (72%) reported indoor tanning infrequently (less than once a month or on special occasions). However, 28% of all tanners tanned at least once per month and 15% reported tanning once a week or more (Table 3).

The reported usual length of a tanning session ranged from 5 minutes to more than 60 minutes. The majority of tanners reported sessions lasting from 21 to 30 minutes (Table 3). Most reported their longest session as 30 minutes. However, 11% of the tanners reported tanning indoors for more than 30 minutes. More than 40% of the tanners reported not always wearing goggles and 17% reported never wearing them. Chi-square tests of association revealed that those who reported longer usual tanning sessions were less likely to use goggles ($P = .06$) and more likely to tan frequently ($P = .02$).

TABLE 3—Practices of Users of Commercial Tanning Facilities

	%
Average length of tanning session (n = 322)	
1–10 min	4
11–20 min	30
21–30 min	63
> 30 min	3

Frequency of sessions (n = 326)	
≥ 1/week	15
< 1/week but ≥ 1/month	13
< 1/month	72

Skin and eye problems were frequently reported by indoor tanners. Approximately 16% of the tanners had experienced one or more eye problems, including pinkeye, eye burns, or sandy or gritty eyes. Fifty-nine percent reported some skin injury, including burned, blistered, or peeled skin and/or rashes.

Tanners were asked to report the instructions and warnings they received

Ever noticed a sign warning of the risks of indoor tanning (n = 301)	48

from operators at the business where they tanned most often. Table 4 shows that more than half were not always told to wear goggles, more than a fourth said they were never told to limit their time per session, half reported that they had never received a warning about the health risks of indoor tanning, and fewer than half had ever noticed a sign warning of the health risks of tanning.

All students were asked to respond to true/false statements regarding the risks of indoor tanning. Sixty-one percent knew that closing their eyes or covering them with cotton balls while tanning was not enough protection, 71% knew that indoor tanning is not safer than natural sunlight, 79% knew that indoor tanning could cause skin cancer, and 77% were aware that damage could occur from tanning even without a sunburn. Only 22% of the students knew that tanning is more harmful to adolescents than adults. The tanners were as knowledgeable as those who had never tanned indoors.

Discussion

Our results indicate that these adolescents, especially females, use commercial tanning devices at high rates, begin tanning indoors at young ages, and often do not engage in protective behaviors. Especially alarming is the number of weekly tanners (15% of tanners) and the number who infrequently or never use goggles while tanning indoors (30% of tanners). Furthermore, it appears that tanning facility operators often do not warn users of the risks of tanning, and the FDA warning is not noticeable to the majority of adolescent tanners.

In Minnesota communities, commercial tanning facilities are readily available. For instance, 33 tanning businesses with a total of 150 tanning beds were located in the suburban area where students included in this survey live, or 1 tanning bed for every 1200 residents.

Despite the health risks associated with indoor tanning during adolescence, many commercial tanning facilities in Minnesota target this population. Indoor tanning facilities often offer a variety of student discounts and promotions, such as price reductions, multiple tanning session packages, advertisements in school yearbooks and student newspapers, and free tanning coupons as prizes at school functions.

Of the 22 states that regulate commercial tanning facilities, only about half require parental consent for use of commercial tanning facilities, and none prohibit their use by minors. This is despite the recommendations made by the American Academy of Dermatology,[3] the American Medical Association,[5] the Skin Cancer Foundation,[18] the American Cancer Society,[19] and the United States Public Interest Research Group[17] for prohibition or severe limitations of use by minors and adults.

The limitations of this study include the use of self-reports about tanning activity, the fact that reports of medical problems were not validated, and the use of a single suburban school as the only data collection site, which limits generalizability. However, these data indicate the potential for widespread exposure to serious health risks in this population. Further studies are needed to explore the prevalence of adolescent use nationwide and to document acute and chronic injury caused by the use of commercial tanning devices. □

Screening for Insecticide Overexposure under Field Conditions: A Reevaluation of the Tintometric Cholinesterase Kit

Rob McConnell, MD, and Ralph Magnotti, PhD

ABSTRACT

A semiquantitative tintometric field kit has been used in the developing world for almost 30 years to measure whole blood cholinesterase levels in persons exposed to organophosphate pesticides. The validity of this screening kit was evaluated among 79 workers heavily exposed to organophosphates by comparison with a reference assay for erythrocyte cholinesterase. Overall correlation between the two methods was good. However, either sensitivity or specificity of the tintometric kit was less than 75% for each of the three tintometric categories commonly used to define the limit of normal. Because baseline erythrocyte cholinesterase levels were not available for this population, the true sensitivity and specificity of the tintometric assay may be even lower. (*Am J Public Health*. 1994;84:479–481)

Introduction

Worldwide, it is estimated that there are approximately 3 million severe poisonings and 220 000 deaths every year due to pesticides.[1,2] Ninety percent of these poisonings and 99% of the deaths occur in developing countries, although these countries account for only 25% of world pesticide consumption.[2]

The measurement of cholinesterase in blood was one of the first biomarkers available as a screening test for a toxic exposure. It is used to identify asymptomatic workers who are overexposed to acutely toxic organophosphate insecticides.[3] In developing countries, an economical, "tintometric" field kit has been available for more than 40 years to measure whole blood cholinesterase activity semiquantitatively in nine intervals (from 0 to 100) as a percentage of the activity of blood from an unexposed control.[4] A previous evaluation of this kit concluded that differences from a standard laboratory assay were "not beyond those which might be anticipated as due to inherent differences in methods."[5] However, the sensitivity and specificity of the kit and its accuracy in identifying workers with mildly depressed erythrocyte cholinesterase were not presented.

In this study we reevaluate the tintometric kit, using as a reference assay a modification of the standard laboratory method (Ellman et al.'s[6]), as adapted for field evaluation of erythrocyte cholinesterase. The diagnostic validity of this assay has been established by laboratory tests and field trials with normal and pesticide-exposed populations.[7,8] In these studies, the assay exhibited a linear response as a function of erythrocyte cholinesterase concentration from 10% to more than 200% of mean normal activity. These measurements were proportional to the response observed on identical codeterminate samples using the method of Ellman et al.[6] ($R > .99$), which is considered to be the standard for cholinesterase assay.[9]

Methods

Seventy-nine male Hispanic workers at rural landing strips and at one large crop-dusting airport in Northern Pacific Nicaragua were examined. These workers' exposures to a wide variety of organophosphate insecticides have been reported elsewhere.[10,11] Each worker was instructed to wash his hands. Then the index finger or thumb was washed with 0.1 normal sodium hydroxide, wiped with 70% ethanol, and allowed to dry. A deep puncture was made with a lancet, and blood was drawn and assayed for whole blood cholinesterase (using the tintometric kit) and for erythrocyte cholinesterase (using the reference assay).

The protocol specified by the manufacturer of the tintometric kit (Tintometer Company, Williamsburg, Va) was followed:[12] the cholinesterase activity of each subject was compared with that of one of two adult male controls, who were unexposed to pesticides. The manufacturer makes the following recommendations for interpretation of the results:

- 100% to 75% of control cholinesterase activity: no action necessary.
- 75% to 50% of control cholinesterase activity: overexposure probable; repeat test. If results are confirmed, suspend subject from further work with organophos-

phate insecticides for 2 weeks; then retest to assess recovery.

- ≤50% of control cholinesterase activity: serious overexposure; repeat test. If results are confirmed, suspend subject from all work with insecticides. If subject is ill, or if results are less than 24% of control activity, arrange medical examination.

The results of the reference assay for erythrocyte cholinesterase were used for evaluating the tintometric kit. The assay was conducted as previously described:[7] 46 healthy, unexposed male health workers were sampled to establish a lower normal 90% confidence limit of 3.7 IU/minute/mL of blood (mean = 4.6 IU; SD = 0.54).

Results

The number of workers in each tintometric (whole blood cholinesterase) category and the mean erythrocyte cholinesterase activity (reference assay) among workers in each tintometric category are presented in Table 1. In a previous comparison of the tintometric method, a similar pattern of increasing mean erythrocyte cholinesterase was seen as the tintometric categories increased.[11] Thirty-eight of the 79 workers (48%) had erythrocyte cholinesterase activity (reference assay) below the lower normal limit of 3.7 IU. Thirty-two of 79 (41%) had low tintometric cholinesterase activity, using tintometric category 75% as the criterion for abnormal. However, in the critical tintometric categories from 75% to 50% of control activity, there was considerable overlap of workers with normal and abnormal erythrocyte cholinesterase activity, as determined by the reference assay (see Table 1 and Figure 1). In addition, although all workers with tintometric activity of less than 50% also had abnormal activity according to the reference assay, 3 of the 29 workers (10%) with tintometric activity of 87.5% or 100% of control activity had low activity according to the reference assay.

The sensitivity, specificity, and predictive value of the tintometric kit were calculated considering as abnormal a tintometric category of 75% or below (Table 2), as recommended by the manufacturer. In this highly exposed population, predictive value positive was only 70%. When tintometric categories 62.5% and 50% were used as criteria for abnormal and the screening parameters were recalculated, sensitivity declined markedly and specificity improved dramatically. Unfortunately, for any of the three tintometric categories (75%, 62.5%, and 50% of control activity), either sensitivity or specificity was less than 75%, and predictive value positive or predictive value negative was less than 80%.

Discussion

Although the overall correlation between the reference assay and the tintometric tests was good, either sensitivity or specificity was less than 75% for each of the three critical tintometric categories commonly used to define abnormal (from 75% to 50% of the tintometric control). In addition, although there is good agreement between the two methods at tintometric values of less than 50% of control activity, in tintometric categories of 87.5% and 100%, 3 of 29 samples were low by the reference assay. According to the tintometric kit's manufacturers, these samples should all be normal.[12] These results are consistent with our previous observation that the tintometric kit substantially

TABLE 2—Sensitivity, Specificity, and Predictive Value of the Tintometric Kit, with the Use of Different Tintometric Categories to Define Abnormal: Crop-Dusting Airports, Nicaragua (n = 79)

Tintometric Abnormal	True-Positive	False-Positive	True-Negative	False-Negative	Sensitivity, %	Specificity, %	Predictive Value Positive, %	Predictive Value Negative, %
75	38	15	26	3	92	63	70	90
62.5	28	4	37	10	74	90	88	79
50	22	1	40	16	58	98	96	71

overestimated cholinesterase activity during recovery from acute poisoning.[7]

Although there is a disturbing lack of agreement between the tintometric cholinesterase assay and the Ellman assay, the results may actually overestimate the accuracy to that kit. The intraindividual variance of erythrocyte cholinesterase over time is much less than the interindividual variance (used in this study to establish a normal range). Because of the wide range of normal values in different unexposed individuals, it is recommended that a preexposure baseline cholinesterase activity be established for each pesticide-exposed worker for subsequent comparison. Any organophosphate-exposed worker whose erythrocyte cholinesterase falls to 70% of baseline should be removed from exposure.[3,13,14] Unfortunately, the tintometric assay does not have sufficient precision to establish such a baseline reliably. There might have been both more false-positive and more false-negative results if preexposure reference baseline levels had been available for these workers. In addition, it should be noted that this was a heavily exposed population with a very high prevalence of workers with depressed cholinesterase according to the reference standard. It is well known that predictive value depends on prevalence in the sample population.[15] In a population with lower prevalence, predictive value positive would decrease.

Caution should be used in interpreting results of this useful biomarker of organophosphate exposure, especially when screening populations with low prevalence of overexposure, unless appropriate validation and rigorous quality control guarantee accuracy. □

Public Health Then and Now

Editor's Comments: Plurality of Views

In view of the timeliness and seriousness of the issues under discussion, the Editors agreed to publish the following exchange between Howard Waitzkin and Alain Enthoven on the history of managed competition. The proposals for health care reform currently under national discussion span a broad range from "single payer" to the unfettered free market, and we recognize that these different proposals inspire strong feelings and opinions. The American Public Health Association has long been a strong proponent of national health care reform and historically has endorsed the principles of the single-payer position. Although the editors of the *American Journal of Public Health* welcome spirited argument on the issues of health care reform, we would like to emphasize that this journal is open to a plurality of views, and we reject any implication that one approach is more "American" than another. □

The Strange Career of Managed Competition: From Military Failure to Medical Success?

Howard Waitzkin, MD, PhD

ABSTRACT

Managed competition remains untested as the basis of a national health program. However, key principles of managed competition first emerged in the military. For this study, published works on systems analysis and the planning-programming-budgeting system (PPBS), developed by Alain Enthoven and colleagues at the US Department of Defense during the 1960s, were compared with published presentations of managed competition. The influence of PPBS waned after it generated controversy and opposition. PPBS and managed competition represent similar managerial strategies of policy reform. Although the origin of managed competition in failed military policy does not ensure failure in the medical arena, this history also does not augur success. (*Am J Public Health.* 1994;84:482–489)

> Beyond its uniqueness and eclecticism, I would like to say that the art of weapon systems analysis, like the art of medicine, should be based on scientific method, using that term in its broadest sense.[1]
>
> —*Alain C. Enthoven, 1963*

Since managed competition as the basis of a national health program remains untested anywhere in the world, by what yardstick should it be judged?

Current debates do not recognize that key principles of managed competition arose historically in a completely different, nonmedical arena: the military. These principles briefly became influential at the US Department of Defense and certain other parts of the federal government. However, this approach to policy-making eventually fell into disfavor because of both its failure to achieve policy goals and the widespread opposition that it generated in the military sector, other administrative branches of government, Congress, and the general public.

The origins of managed competition in military policy help clarify what can be expected from a similar managerial strategy of health care reform. Through a critical review of published works, this article traces the history of managed competition, compares complementary themes in the military and medical arenas, and presents implications for future decisions about a US national health program.

Origins of Managed Competition in Military Policy Analysis

The conceptual framework of managed competition originated in the military situation that confronted the United States during the Cold War of the late 1950s and early 1960s. Professor Alain Enthoven, an economist and the princi-

pal intellectual architect of managed competition, was a driving force behind systems analysis at the Pentagon between 1961 and 1969, and his conceptual approach to health care owes much to the analytic work that he and his colleagues carried out during that period. Military systems analysis and managed competition in health care represent similar managerial approaches to policy reform.

After John F. Kennedy became president in 1961, he appointed Robert McNamara, chief executive officer of the Ford Motor Company, as secretary of defense. An advocate of strong management, McNamara selected Charles Hitch, an economist based at the RAND Corporation, as assistant secretary of defense. While at RAND during the 1940s and 1950s, Hitch had spearheaded the Economics Division, which was funded mainly by the Air Force and whose purpose was to apply economic analysis to choices of weapon systems and strategies; this work at RAND culminated in an influential book that spelled out how economic analysis could guide defense policy decisions.[2] Hitch brought with him to the Pentagon several colleagues from RAND, including Enthoven, who helped establish the Office of Systems Analysis and later also rose to become assistant secretary of defense. Enthoven presented the accomplishments of this office in a series of articles appearing in military and economics journals during the 1960s, as well as in two books.[3,4]

At the Pentagon, Enthoven and his coworkers emphasized the planning-programming-budgeting system (PPBS) and cost-benefit analysis.[4] PPBS aimed to develop "plain statements" of national purposes in defense programs. Based on such formulations, each defense program could be evaluated and compared with alternative programs aimed at achieving the same purposes. In considering military goals, this approach tried to express costs and benefits quantitatively (see photo). An independent analytical staff, composed mostly of civilian specialists such as economists, prepared technical reports comparing the alternatives that the secretary of defense and other key officials used in decision making. The independence of this staff was viewed as essential to balance the narrow interests of military officers, defense contractors, and politicians who sought to influence decisions.

As systems analysis gained prominence, several policy decisions reflected the impact of PPBS. These decisions concerned deployment of troops in the North Atlantic Treaty Organization; development and proliferation of nuclear weapons; and initiation of new bombers, missiles, and other weapon systems.[4] Because of the apparent rationality and high-level sponsorship of this approach, President Lyndon Johnson in 1965 mandated the gradual implementation of PPBS throughout the federal government.[5]

At various points in the Vietnam War, systems analysts sought to train military officers through hypothetical exercises such as the evaluation of resupply operations by ground versus air.[6] According to Enthoven, PPBS also contributed to the war effort by evaluating troop deployment plans, developing alternatives to "body counts" as measures of success in the war effort, estimating aircraft attrition, and measuring progress in the Vietnam "pacification" program. But despite its attempt to reform military policies through a strategy of strong and rational management, systems analysis generated controversy and opposition both within and outside government, and its influence began to wane as US participation in the Vietnam War increased during the late 1960s.

In a retrospective account, Enthoven and K. Wayne Smith, a colleague at the Pentagon, acknowledge this opposition.[4(pp267–308)] Administrators of other cabinet-level departments did not consistently implement President Johnson's mandate. Professional military leaders, defense contractors, and civilian analysts at the Pentagon were antagonistic toward PPBS. Politicians in Congress grew impatient with quantitative analyses of defense policies (see photo of Gardiner L. Tucker).[4(pp309–313)] Antiwar activists argued that cost-benefit analysis led to inappropriate policies because it clouded the ethical dimensions of important decisions, especially those about nuclear weapons and Vietnam. But despite its claimed advantages in cost controls, PPBS did not prevent or modulate a rapid increase in military expenditures, which remained unsurpassed until the mid-1980s (Figure 1).[7(p336)] This rate of increase in military expenditures during the 1960s reflected the pressures of the Vietnam War and concerns about nuclear conflict, and PPBS was not in a position to control overall costs in the context of these broad political forces.

DR. ALAIN ENTHOVEN
He tells the military what's right.

Alain C. Enthoven lecturing on systems analysis in the military, 1963. On the chalkboard, the vertical axis is labeled "targets destroyed" and the horizontal axis is labeled "$." Reprinted with permission from Time, Inc.[50]

Thus, while Enthoven and his associates continued to defend PPBS, they acknowledged that their principles had little impact on military policies during the late 1960s. Accordingly, Enthoven's retrospective view conveys disappointment and failure:

> The Systems Analysis office did not have a prominent, much less a crucial, role in the Vietnam war. . . . It had no policy role in determining the overall totals of men to send to Vietnam, or in figuring out what they should do when they got there. . . . If we make no other point in this book, we want it to be clear that the full value of systematic analysis in making decisions on the conduct of a war has yet to be tested.[4(p270)]

Already in eclipse, PPBS continued to lose prominence in policy-making, and its impact in other spheres of government remained minimal. As Enthoven and Smith point out, President Richard Nixon promised to "root out the

whiz kid approach at the Pentagon."[4(p333)] Although the Office of Systems Analysis survived, its activities became much more circumscribed. Temporary decreases in military spending during the mid-1970s mostly reflected the scaling back of operations in Southeast Asia rather than the impact of PPBS, which by that time contributed in a very minor way to budgeting at the Pentagon. PPBS did not enjoy a comeback under the administration of Jimmy Carter, and it remained uninfluential during the peacetime military buildup of the Reagan and Bush administrations.

After a brief excursion into private industry between 1969 and 1973 as vice president and then president of Litton Industries, a major military contractor, Enthoven then joined the faculty of Stanford University in 1973 as a professor of both management and health care economics.[5] There his work on health policy incorporated the principles of management and systems analysis that he had previously advocated at the Pentagon.

By 1977, only 4 years after leaving the defense sector, Enthoven offered to the Carter administration a proposal for a "Consumer Choice Health Plan," based on regulated competition in the private sector. This proposal built in part on prior initiatives by Paul Ellwood for a national health maintenance strategy and by Scott Fleming for structured competition within the private sector.[9(pp65–67)] Although Carter rejected the plan, Enthoven soon afterward published the proposal in the medical literature[10] and in a separate monograph.[11] In this early work, Enthoven presents the basic conceptual structure of all subsequent proposals for managed competition. As discussed later, this proposal for health care reform contains important concepts from the military policy work that Enthoven had spearheaded a few years earlier at the Pentagon.

During the 1980s, Enthoven collaborated with Ellwood, other proponents of health maintenance organizations (HMOs), corporate executives, and officers of private insurance companies in refining the proposal. An emphasis on managed competition arose during the mid-1980s in response to concerns raised by economists and business leaders that the original proposal conveyed free-market assumptions requiring modification through closer "management" of the program.[12] The new name also conveyed a message of managerial control that proved attractive to business leaders.

After publication of a revised proposal in 1989,[13] the coalition supporting managed competition broadened to include officials of the largest US private insurance companies, which were diversifying into managed care. These business leaders met regularly with Enthoven and other proponents of managed competition at Ellwood's Wyoming home as part of the so-called Jackson Hole group. The managed care sector of the private insurance industry provided major funding for this group, as well as financial and logistic support for Bill Clinton's presidential campaign and consultation for the Presidential Health Care Task Force.[14,15]

Most recent proposals for managed competition—including that of the Clinton administration—have emerged from this intellectual tradition. These proposals use fixed premium contributions by employers and government to encourage enrollees to choose less expensive plans; the proposals also use price competition among health plans to help control fees paid to doctors and hospitals.[16,17] Certain proposals have suggested modifications in the conceptual structure outlined by Enthoven and his colleagues. For instance, although managed competition traditionally has encouraged employer-sponsored plans with participation by private insurance companies, other proposals have separated employment from insurance through the creation of a single, tax-financed, globally budgeted public fund, which would contract with private plans for a minimum benefit package.[18–20] All managed competition proposals, however, incorporate concepts initiated by Enthoven and his colleagues, and all of them call for large-scale changes in the ways medicine is practiced and choices are made by physicians and consumers.

Complementary Themes in Military and Health Policy

As has been seen, the theoretical advantages of strong management techniques, as advocated by Enthoven and his colleagues, did not lead to enduring improvements in defense policy. This failure derived not only from the self-interested opposition of military officers and members of Congress, but also from the limitations of PPBS in addressing the political and ethical dimensions of major public policy decisions. Because the theory of managed competition in health care, which seems to be heading for its possible first test, contains unmistakable elements of PPBS, the limitations and complementary themes in these two approaches to public policy merit closer critical scrutiny than they have received thus far. Table 1 summarizes these themes.

Distrust of Professionals

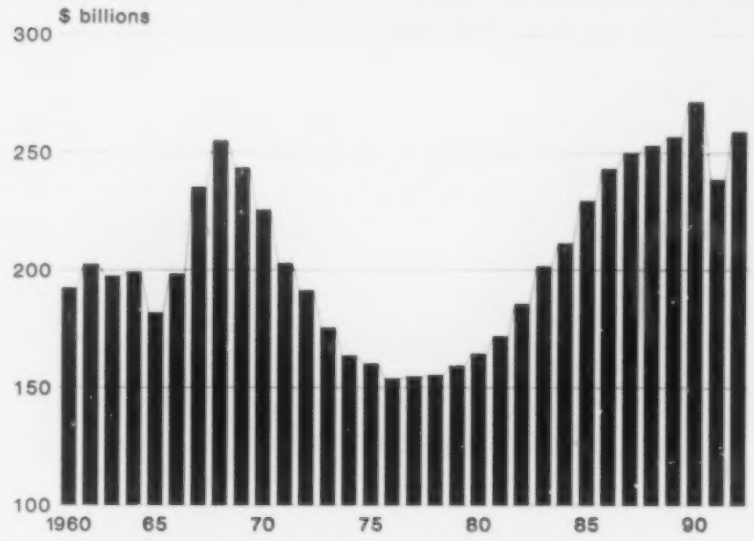
PPBS argued that professional military officers held vested interests that led them to advocate ever-expanding investment and program development in their own narrow areas of expertise. For instance, the chiefs of the army, navy, and air force promoted new weapon systems with little critical appraisal of those systems' contribution to the national interest and without coordination among the services. While expressing formal respect for the professional competence of military officers, Enthoven and other proponents of PPBS argued that defense policy must counterbalance the vested interests of military brass through technical analyses of costs and benefits performed by civilian personnel. Independent analysts were needed to foster informed and cost-conscious defense policy decisions.[4(pp42–44)]

In managed competition, distrust of professionals manifests itself in a very critical assessment of physicians' vested interests. According to Enthoven, physicians function as a guild, which reduces the ability of market forces to control costs or encourage quality. From this perspective, the guild structure permits free choice of doctor by patient, free choice of prescription by doctor, direct negotiation between doctor and patient regarding fees, payment based on fee-for-service, solo practice, and professional control over medical licensure.[9,10] Managed competition, on the other hand, calls for concerted action by independent analysts and purchasers to curb decision-making power based on physicians' professional self-interest.

Trust of Managers

In arguing for the role of civilian analysts at the Department of Defense, Enthoven and his colleagues placed confidence in "active management at the top." In this model, implemented at the Pentagon, the secretary of defense received proposals about programs and weapon systems from military officers through the joint chiefs of staff. But independent analysts then subjected these proposals to rigorous analysis of costs and benefits in light of precise statements of the national interest. Memoranda prepared for the president presented conclusions of these analyses, thus encouraging more informed and objective decision making.[4(pp73–116)] Throughout this process, it was assumed, civilian managers would prove less guided by vested interests than would the professional brass.

Likewise, the wisdom of managers mostly based outside the medical profession has emerged as a basic tenet of managed competition. Under this approach, the locus of decision making moves from the medical guild to a cadre of managers, who administer the organizational "sponsors" of group health plans. (Under recent proposals, these sponsors are called "health insurance purchasing cooperatives" or "health alliances.") Incentives encourage physicians to organize themselves into competing economic units. Managers of the sponsors, which could include employers, labor-management health and welfare trusts, the federal Medicare system, state governments, and other large organizational entities, make prudent choices among competing plans on behalf of individuals and families. Guided by managerial principles, the sponsors serve as "active, intelligent, collective agents on the demand side who structure and adjust the market in a continuing, but never completely successful, effort to overcome its tendencies to failure."[9(p75)]



Note. Military expenditures increased rapidly during the 1960s, including the early years of the Vietnam War, when PPBS, which encouraged cost-conscious policy decisions, was in effect at the US Department of Defense.

FIGURE 1—Growth in US military expenditures, in constant (1982) dollars, from 1960 to 1992.

TABLE 1—Complementary Themes in Military Planning-Programming-Budgeting System (PPBS) and Managed Competition in Health Care

Theme	Focus of Theme	
	PPBS	Managed Competition
Distrust of professionals	Military brass	Medical guild
Trust of managers	Independent analysts	Managers of organizational sponsors
Choice among competing alternatives	Weapon systems, military strategies	Organized health plans
Scientific method	Cost-benefit analysis in case studies	Cost-benefit analysis in case studies
"Tools" for managers	Cost-benefit analysis, 5-year defense plan, draft presidential memos, development concept papers	Techniques to prevent "market failure": pricing, cost-benefit analysis, annual enrollment, quality assurance, subsidy management
Incrementalism with strains	Military officers, corporate contractors, members of Congress	Physicians, middle-class consumers, private insurance companies not equipped for managed care
Cost analysis but not necessarily cost reduction	No budget ceiling for military expenditures	No budget ceiling for health care expenditures

TABLE 2—Example of the Planning-Programming-Budgeting System as Applied to Nuclear Weapons: Comparative Effectiveness of Two Hypothetical Missile Pay Loads,[a] by Number of Targets Destroyed

Type of Target Destroyed	Ten 50-Kiloton Warheads Totaling One-Half Megaton	One 10-Megaton Warhead
Airfield	10.0	1.0
Hard missile silos	1.2–1.7[b]	1.0
Cities of 100 000 population	3.5	1.0
Cities of 500 000 population	0.7	1.0
Cities of 2 000 000 population	0.5	0.6

Source. Reprinted with permission from Enthoven and Smith.[4(p182 Table II)]
[a]Both assumed to be reliably delivered.
[b]Variation depends on target hardness, delivery errors, and number of warheads allocated to each silo.

This view also calls for a reduction in decision-making discretion for individuals and families as consumers of services. Because of technical complexity, managers assume a paternalistic role in making rational decisions on behalf of consumers. As Enthoven writes: "This isn't a market in which the invisible hand will do the job. Some visible hands, which I call sponsors, must manage the demand side to make the market achieve desirable results."[9(p113)] Managerial input would shape not only the range of health plans offered to consumers but also the basic benefits package. Like PPBS, managed competition places faith in the ability of technically oriented managers to make decisions that are independent of any particular interest group. Thus, as decision making moves to high-level managers, managed competition is expected to foster administrative authority wielded in an enlightened effort to reconcile the interests of physicians, patients, business, and government.

Choice among Competing Alternatives

PPBS sought to analyze the marginal costs and benefits of competing alternatives to similar policy goals so that high- level managers could make informed choices. In the case of nuclear weapons, Enthoven and his colleagues tabulated hypothetical data on the projected number of enemy cities destroyed by multiple warheads, each containing a relatively small nuclear payload, as opposed to fewer warheads, each with a much larger payload (Table 2). Through these tabulations, it became apparent that multiple warheads with smaller payloads would prove more cost-effective since more cities with larger cumulative populations could be destroyed for a given level of investment in nuclear weapons.[4(pp165–195)] In the context of Cold War pressures, this analysis coincided with one of the largest overall buildups of nuclear weapons in history, and the ethical dimensions of such policy alternatives received very little attention.

By a similar logic, managed competition encourages the development of competing health plans, among which managerial sponsors would choose on behalf of consumers. In making informed choices, managers would consider data on the relative costs and benefits of competing alternatives. In some instances, choice would also be offered to consumers, but they would have to pay more for health plans that provide benefits beyond the basic minimum package. The main locus of choice, however, will reside with the managers of large organizations that contract with competing health plans. From this viewpoint, the theoretical advantages of managerial choice are seen as superior to alternative policies such as a single-payer system, which controls costs through monopsony financing while permitting substantial choice for individual patients and doctors.

Scientific Method

At the Pentagon, PPBS introduced quantitative, cost-oriented analyses into policy deliberations. This approach conveyed scientific rationality, as opposed to prior procedures that were based on subjective opinion and the power positions of military and congressional leaders. A frequently used method of analysis was the case study, such as the study of nuclear warheads and payloads cited above, in which the costs and benefits of alternative weapon systems or military strategies were compared. The complexity and esoteric features of such studies tended to make them inscrutable to military officers and congressional representatives unschooled in economics.[4(p62)] For policymakers, decisions often involved nonquantifiable considerations, mostly value judgments, which proponents of PPBS referred to as "imponderables."[2] Further, PPBS required assumptions that simplified complex realities of military operations. Analysts at the Pentagon often used theoretical or hypothetical exercises that, despite their sophistication, proved much less useful than hoped in guiding concrete operational decisions, such as the deployment and resupply of equipment in Vietnam.[6]

The aura of scientific method also pervades arguments on behalf of managed competition. Again, rather than calling for more powerful scientific methods, such as random controlled trials on a regional or state level, to evaluate managed competition as opposed to single-payer or other policies, Enthoven uses case studies selectively to justify key claims. For instance, he uses the Kaiser system as a case study to demonstrate the cost-saving potential of HMOs.[9(pp42–58),10(pp68–69)] In this case study, however, Enthoven downplays prior and subsequent evidence showing that, in contrast to Kaiser, most managed care organizations, such as independent practice associations and preferred provider organizations, have not shown consistent cost savings.[21–23] He and other proponents of managed competition also cite certain cost reductions noted for prepaid group practices within the RAND health care experiment, but they do not emphasize that this random controlled trial did not evaluate managed competition per se.[13] In his case study of Kaiser, Enthoven also does not address data that show similar or lower levels of patient satisfaction in HMOs than in fee-for-service settings.[24–26] Similarly, he uses Canada as a case study and alludes to the work of economist Robert Evans,[27] which showed increases in payments to physicians under Canada's national health program; however, while Enthoven cites a small facet of Evans' work to argue against a single-payer

system,[9(p36)] he does not refer to the larger corpus of Evans' or other investigators' work that has yielded favorable evaluations of the Canadian system.[28–31]

The science of managed competition therefore remains based in theories of market forces and selective application of case studies, rather than in evaluation using more powerful methods available in health services research. Like PPBS before it, managed competition thus becomes a set of scientifically oriented principles to be implemented without prior scientific test.

"Tools" for Managers

New analytic "tools" became corresponding elements of both PPBS and managed competition. In PPBS, chief among these tools were the hypothetical case studies that considered costs and benefits of alternative policies, especially regarding weapon systems. Other tools introduced by Enthoven included a 5-year defense plan, draft presidential memoranda, and development concept papers that presented competing policy options for executive decision.[4(pp48–60)] Efficacious military policies depended on the disciplined use of these tools by systems analysts and their superiors in top management.

The tools of managed competition, again envisioned mainly by Enthoven, are techniques that managers of organizational sponsors can use to counteract "market failure." These tools include methods of pricing, construction of standardized benefit packages based on analysis of projected costs and benefits, annual enrollment and disenrollment procedures, quality assurance methods, management of subsidies, and various "pro-competitive actions" that restrict the economic power of health care providers.[9(pp98–118)] A manager's task would be to use such tools to reduce the impact of market failures, such as continuing access barriers, selection of low-risk enrollees, and cost overruns. Practical impediments to using these managerial tools remain understated, as was the case with similar tools at the Pentagon.

Incrementalism with Strains

Proponents of PPBS acknowledged that their methods implied drastic changes in military policy-making. Incrementalism, the only route ideologically acceptable in the "free world," comprised the process by which advocates believed such changes would occur.[32,33] Career officers, corporations that received military contracts, and people in Congress who supported the traditional way of doing business experienced the inevitable "strains" of incremental change. Military and congressional resistance to such strains eventually contributed to the decline of PPBS as a managerial technique in government. Again, PPBS proved unrealistic in its assessment of US political realities as it underestimated the difficulties of achieving fundamental policy shifts through slow, incremental processes.

Under managed competition, the guild of medical professionals, patients unaccustomed to making cost-conscious decisions, and private insurance companies unequipped for managed care would experience the main strains of change, which again would occur through an incremental process. Arguing that "incrementalism is a fundamental law of behavior in democratic governments," Enthoven advocates a coordinated strategy to "break up the medical guild."[9(pp119–124)] This strategy includes legislation that permits selective contracting with preferred providers, outlaws boycotts by physicians, prohibits price fixing, and restrains other "concerted refusals to deal" by medical professionals. To achieve the widest impact, Enthoven suggests that incremental reforms start with the "educated middle class," who are already accustomed to cost-conscious choices. In discussing incrementalism, however, Enthoven again tends to downplay opponents' ability to undermine processes of slow, incremental change. Moreover, he and his colleagues also discount an alternative view of social change: that democratic societies are capable of making fundamental changes rapidly and successfully, as happened when the United States implemented Social Security in 1935 or when other countries enacted single-payer national health programs.

Cost Analysis but Not Necessarily Cost Reduction

While it analyzed competing alternatives in terms of costs and benefits, PPBS never promised to reduce costs overall. Aiming to achieve the "fullest value per dollar spent,"[5] its advocates viewed PPBS as a better way to manage that was compatible with higher, lower, or unchanged costs. For instance, Hitch noted that cost-benefit analysis remained neutral regarding the unit cost of a particular weapon system.[34] In arguing for explicit consideration of both costs and needs, Enthoven opposed arbitrary budget ceilings that would restrain overall increases in military expenditures.[4(p203)] As previously noted, PPBS coincided with an unprecedented rate of growth in military spending (Figure 1).

Similarly, proponents of managed competition are careful to note that it will not necessarily lower health care costs. Again opposing a cap on overall expenditures, Enthoven favors, on theoretical grounds, market forces that encourage cost-conscious choices, with a goal of maximizing value for money. He and his colleagues predict short-term increases in health care expenditures, as the costs of new layers of administration are added to those of expanded services for the currently uninsured. While longer-term savings may result from managerial decision making, Enthoven and his colleagues acknowledge that such savings remain largely hypothetical and will take years of organizational change to achieve.[9(pp119–135)]

Conclusion

Managed competition has had a strange career. Although this approach remains untested as the organizing principle of any other country's national health program, its intellectual progenitor enjoyed a brief heyday in military policy. By developing and promoting PPBS at the Pentagon, Enthoven and his colleagues worked through many of the economic and analytic procedures later resurrected in the theory of managed competition. In lieu of other yardsticks to evaluate the claims of managed competition, the history of PPBS provides a sense of what may lie ahead in health care.

PPBS failed as a coherent approach to military policy—a failure that deserves attention as managed competition, a similar managerial strategy of reform, gains ascendancy in health policy. PPBS unrealistically gauged the political and ethical dimensions of major public policies. Generating widespread opposition among military professionals, corporate contractors, members of Congress, and peace activists, this managerial strategy of reform exerted little long-term impact on military operations and expenditures or on other spheres of

public administration. Similarly, professional opposition has undermined managed care initiatives in several European countries, both earlier in this century and more recently[35,36]; thus, it is unlikely that medical professionals and their organizations in the United States, seldom lacking in ingenuity in the past, will accept without resistance the administrative control that managed competition here promises to enact. Moreover, the touted advantages of PPBS and managed competition in scientific method, expanded choice, and cost-conscious decisions by high-level managers have not achieved prior successes in policymaking at the national, regional, or state level. Incrementalism with strains, seen as the process of change under both PPBS and managed competition, reflects an ideological, or at least debatable, view of historical processes. The analytic tools of PPBS and managed competition have not lowered overall costs in either the military or medical sector, nor were they intended to do so. Although the origin of managed competition in failed military policy does not guarantee failure in the medical arena, this history also does not augur success.

Aside from this history, both supporters and opponents have raised major concerns about managed competition.[37–41] Demographic limitations would restrict its impact since about 30% of the US population live outside metropolitan areas that could support three or more competing managed care plans. Whether managed competition could control costs remains unclear; states with the most extensive managed care programs have shown costs to be as high as or higher than elsewhere.[42–44] Moreover, administrative costs, already more than 20% of overall health care expenditures,[45] likely would increase still further since managed care is administratively intensive and new organizational sponsors would introduce additional managerial layers. Despite a laudable intent to use research on effectiveness and outcomes to define the uniform minimum benefits package and to assess quality of care, such research has produced verified data about only a small number of medical conditions and procedures. Although "outcomes research" may be construed as increasing professional accountability, proposals for managed competition have not clearly described who would carry out such research or whether access to data would remain within the public domain and in usable form. How practice guidelines would achieve accountability within for-profit entities that compete on the basis of price, while not alienating providers and patients, remains unclear.

Several practical concerns have also arisen regarding the acceptability of managed competition to providers and consumers.[15,36] While expanding the decision-making power of large insurance companies that already have entered the managed care field, managed competition probably will reduce consumers' freedom to choose practitioners, and micromanagement of clinical decisions likely will increase. Because the ability to buy additional coverage beyond the basic benefits package will depend on income, this provision will perpetuate unequal, multitiered coverage. Whether managed competition will succeed in curbing insurance companies' selection or exclusion of patients by risk of costly illness remains in doubt. Managed competition likely will create higher out-of-pocket payments and taxes for a substantial part of the population who currently are insured. Several polls have shown less public support for managed competition than for other alternatives.[46] Evidence that managed competition would solve the access problem while controlling costs remains less convincing than evidence that exists in support of a single-payer option.[47,48] For instance, the US Congressional Budget Office has reported that prospects for cost containment under managed competition are uncertain at best and that the only countries that have successfully contained costs are those using single-payer financing.[21]

The powerful coalition built up around managed competition may succeed in enacting this policy. Although it may address some of the concerns raised about managed competition, the Clinton team is unlikely to change the basic structure of the proposal. This reluctance to consider other options seriously may stem partly from the support that the Clinton campaign received from the managed care sector of the private insurance industry,[14,15] as well as from a perception that simpler and more popular options, including a single-payer approach, are unlikely to pass in Congress.

Failure to achieve a workable national health program would generate great disappointment as well as financial waste. Some analysts believe that failure of managed competition is a necessary step toward adoption of a simpler approach such as a single-payer option. A less sanguine view holds that the United States may get only one chance to establish a workable program during this decade and that failure would lead to retrenchment, cutbacks, and a return to the present paradox of pervasive access barriers coupled with high costs.

Ultimately, should market principles of competition, derived largely from failed attempts at managerial reform of military policy, be accepted as cornerstones of national health policy? It is unnecessary to expound on the ways in which health care differs from military procurement. But having emerged historically from military policy analysis, managed competition contains assumptions about the superiority of managerial decision making and discretion, even as they are applied to the micromanagement of clinical processes. Such assumptions about managerial wisdom may lead medicine down a path inconsistent with the aspirations of many health workers and patients. Rather than Enthoven's equation of the art of weapon systems analysis and the art of medicine, an alternative vision might be Wendell Berry's:

> Rats and roaches live by competition under the law of supply and demand; it is the privilege of human beings to live under the laws of justice and mercy. It is impossible not to notice how little the proponents of the ideal of competition have to say about honesty, which is the fundamental economic virtue, and how *very* little they have to say about community, compassion, and mutual help.[49(p135)] □

Acknowledgments

This study was supported in part by grants from the Poverty and Race Research Action Council (Washington, DC) and the US Health Resources and Services Administration (PE 19154).

I thank Stephany Borges, Carolyn Clancy, David Himmelstein, Don Light, Vicente Navarro, Steffie Woolhandler, members of the Health Services Research Seminar at the University of California–Irvine, Elizabeth Fee, and anonymous Journal reviewers for helpful comments on an earlier draft of this article. I am grateful to Michelle Stone and Wendy Wagner for bibliographic assistance.

The ***American Journal of Public Health*** (*AJPH*), published monthly, is the official Journal of the American Public Health Association, Inc, 1015 15th St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005. *AJPH* allotted $40; *The Nation's Health* allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters. Printed in the United States.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on the first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, *AJPH* Reprints, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the Journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Medicaid Physician Payment Reform: Using the Medicare Fee Schedule for Medicaid Payments

Anne Lenhard Reisinger, PhD, David C. Colby, PhD, and Anne Schwartz, MHS

ABSTRACT

Objectives. The purpose of this article is to provide estimates of the costs of basing Medicaid physician payment levels on the new resource-based Medicare Fee Schedule. Two possible policy options are considered: setting all Medicaid physician fees at the Medicare Fee Schedule level and setting only office visit fees at the new Medicare levels.

Methods. Data on Medicaid physician fees, use patterns, and the Medicare Fee Schedule are used to develop state-level estimates of expenditure changes under each option.

Results. Setting Medicaid rates at the Medicare Fee Schedule level could increase expenditures by $3.2 to $4.1 billion nationally; the other option would result in substantially lower increases in expenditures. Because of the current variations in Medicaid physician fees and in the breadth of eligibility across states, the cost of adopting the Medicare Fee Schedule varies considerably among states.

Conclusions. Adopting the new Medicare Fee Schedule for Medicaid payments, proposed by policymakers as a way to increase access to appropriate medical care, could double physician expenditures in some states. Adoption of more limited versions of the fee schedule might achieve some access gains at lower costs. (*Am J Public Health.* 1994;84:553–560)

Introduction

The Clinton administration's commitment to expand access to medical care and contain the growth in medical care costs has accelerated the debate over health care financing reform. Reform will no doubt include changes in the structure of the Medicaid program, although the scope of these changes is uncertain. While national reform could eliminate Medicaid as it currently exists, it more likely will change the program incrementally, gradually eliminating the differences between Medicaid and other insurance plans. This article discusses the cost of one such incremental change, the implementation of a resource-based physician fee schedule like that used in the Medicare program.

Medicaid was enacted in 1965 to improve the existing Kerr-Mills medical assistance program, expanding eligibility beyond the elderly to include other low-income Americans and increasing the federal share of program financing. Over the past 28 years, however, the program has grown beyond its original purpose. Today, Medicaid is viewed by many as a mechanism for increasing access to mainstream medical care for low-income Americans.

Although barriers to mainstream care remain, the Medicaid program has been largely successful in increasing access to health care services and improving the health status of those enrolled in the program.[1] After other differences have been controlled, the eligible poor receive more physician visits, more admissions to the hospital, and more hospital days than poor persons not covered by Medicaid.[2] When beneficiaries' eligibility for Medicaid terminates or when there are program cuts, access to health care diminishes and health status deteriorates.[3,4]

Despite these successes, there are problems with the Medicaid program. Expenditures for the program are rising rapidly and are expected to double between 1990 and 1995. Only about half of the poor are eligible for Medicaid, and the extent of coverage varies by state.[5,6] Moreover, even the enrolled poor are not guaranteed access to medical care; beneficiaries often find it difficult to locate a physician who will provide services, because many Medicaid fees are low.

Recently Congress passed legislation that ameliorates some of these problems. Medicaid eligibility has been expanded. For example, states are required to share Medicare costs for Medicare beneficiaries whose incomes are below the poverty line. States are required to provide Medicaid eligibility to pregnant women and children under 6 years of age in families with incomes at or below 133% of the poverty level and to all other children who live in families with incomes at or below the poverty line. With regard to physician payment, the Omnibus Reconciliation Act of 1989 required that states provide documentation that payment rates for obstetric and pediatric services were sufficient to ensure access comparable to that of the general population.

Policymakers are now considering a number of strategies for solving other problems with the Medicaid program, including changes in Medicaid physician payments. The available empirical evidence suggests that raising physician fees may encourage the provision of office-based physician services in lieu of hospital outpatient department and emergency room care. If changes in fee levels encourage physicians to treat more Medicaid patients in more appropriate settings, physician payment policy

Anne Lenhard Reisinger is with the School of International and Public Affairs, Columbia University, New York, NY. David C. Colby and Anne Schwartz are with the Physician Payment Review Commission, Washington, DC.

Note. The views expressed are the authors', and no endorsement by the Physician Payment Review Commission is intended or should be inferred.

may simultaneously address but will not entirely solve the problem of access for Medicaid beneficiaries.

The enactment of the resource-based Medicare Fee Schedule has created an impetus for similar reforms in Medicaid. Adoption of the Medicare Fee Schedule for Medicaid physician payment would have the advantages of increasing the overall level of payment and of realigning relative payments for primary care services and procedural services.

This article discusses the costs of two options for Medicaid physician payment reform based on the Medicare Fee Schedule. These options, which establish various floors on Medicaid physician payments, are adopting the full Medicare Fee Schedule and applying the Medicare Fee Schedule only to specific services such as visits.

Medicaid Physician Payment and Access to Care

Both academic and policy research have demonstrated access problems for Medicaid beneficiaries, especially in states with low fees. A 1990 survey of state Medicaid directors indicated that low physician participation is a problem for many states. Forty-three states identified participation problems, and more than half (27) identified problems with both geographic and specialty distribution of participating physicians.[7] Other data sources confirm variation in Medicaid physician participation by geographic area and specialty.[8,9]

Although there are a number of reasons why physicians limit their Medicaid participation, 30 states reported that low physician fees are the primary reason for low participation. The high cost of malpractice insurance premiums and complex billing procedures were also thought to be important causes of low participation.[7]

Health service researchers have demonstrated that low physician fees discourage physician participation in the Medicaid program. Higher Medicaid fees increase both the likelihood that a physician will treat Medicaid patients and the number of patients a physician treats.[10–17]

The positive effect of higher Medicaid fees on physician participation suggests that Medicaid and other insurers compete for physicians through their fees. When competing insurers pay higher fees than Medicaid, physicians are less likely to treat Medicaid patients.[12–14,16–18] This does not mean, however, that Medicaid patients will go without care. Rather, they may find other physicians who are willing to treat them, such as those with high-volume Medicaid practices, or they may obtain their care in other settings such as hospital outpatient departments, emergency rooms, and local health department clinics.

The extent of physician participation in Medicaid is a proxy measure of beneficiary access to care. Research that has directly measured the effect of fee levels on beneficiaries' use of medical care suggests that while Medicaid physician fee levels are not related to the number of services Medicaid beneficiaries receive, they are predictive of the site of service. Beneficiaries in states with higher fees are more likely to receive services in physicians' offices, while beneficiaries in states with lower fees are more likely to receive services in emergency rooms or outpatient departments.[19–22] This prompts concern because care provided in emergency rooms or outpatient departments is more expensive than that provided in physicians' offices and does not promote continuity of care.[23,24] In addition, inappropriate use of emergency rooms results in overcrowding, increased waiting times, and restricted access to care in that setting.[25–27]

As Congressman Henry Waxman has noted, "merely having a Medicaid card does not, in and of itself, assure access to physician services."[28] Since Medicaid purchases physicians' services in the fee-for-service market, both the level of physician fees and administrative procedures influence whether physicians will choose to treat Medicaid beneficiaries and how many they will treat.

Physician Payment Options: Adopting the Medicare Fee Schedule

Raising Medicaid fees would improve access to care provided in physicians' offices and provide mainstream care at lower costs per unit of service. Setting Medicaid fees at Medicare Fee Schedule levels would involve two major changes in Medicaid payments to physicians. First, it would require raising most fees in most states. Second, Medicaid payments to physicians would be based on resource costs. Under the Medicare Fee Schedule, Medicare fees for evaluation and management services (visits and consultations) have increased; fees for surgical and other technical procedures have decreased. Relative Medicaid physician fees would probably experience similar shifts.

Beneficiary access will improve if physicians respond to increases in fees by increasing their Medicaid participation and providing more office-based services to Medicaid beneficiaries. The extent of such improvements may vary among states because of differences in current payment levels. Access gains could be larger in states with particularly low Medicaid fees.

Equity among physicians might also be improved by reducing the current economic disparity between physicians with substantial Medicaid caseloads relative to their peers. Administratively, this would relieve Medicaid programs from the burden of setting fees.

The costs of physician payment reform options will weigh heavily in the debate over reform. States, already burdened with escalating Medicaid expenditures, may be reluctant to adopt reforms that increase those costs even more. Since Medicaid expenditures for physician services constitute only about 6% of total Medicaid expenditures, the financial impact of these options is relatively small. The following section estimates the initial costs of two physician payment reforms that would link Medicaid payments to the Medicare Fee Schedule.

Estimating Expenditure Changes

Estimated changes in Medicaid expenditures were calculated separately for beneficiaries dually eligible for Medicaid and Medicare and for all other beneficiaries. The two populations were separated because states are responsible for the full payment for nondually eligible beneficiaries and may elect to pay the 20% Medicare copayment for dually eligible beneficiaries. Twenty-four states pay the full Medicare coinsurance for dually eligible beneficiaries; the other states and the District of Columbia pay Medicare coinsurance for fees up to state Medicaid fee levels.

Nondually eligible beneficiaries. Data from Health Care Financing Administration (HCFA) Form 2082 were used to estimate expenditures for this population. Since expenditures on Form 2082

were for 1991, they were inflated to reflect the actual expenditures in 1992 (as recorded on HCFA Form 64).

The price difference between Medicaid and the Medicare Fee Schedule was measured by an index of the ratio of Medicare Fee Schedule to Medicaid fees for the same physician services averaged across nine service families. (Because Medicaid physician fees for only 16 services were used, fees were grouped into families to allow generalization from several fees to larger groups of services. The estimations therefore assume that these few fees represent a much larger set of services. The service families are office visits, hospital visits, emergency room visits, consultations, psychiatric services, electrocardiograms, x-ray services, obstetrical services, and surgical services and other procedures. Average Medicaid and Medicare Fee Schedule fees for each family of services were estimated on the basis of one or several physician services. The service families included the following Current Procedural Terminology (CPT) codes: limited [90050], intermediate [90060], and comprehensive [90020] office visits; initial [90220] and subsequent [90260] hospital visits, emergency room visits [90515]; initial consultation [90620]; individual psychotherapy [90844]; electrocardiogram [93000]; chest x-rays [71020, global fee and professional component]; vaginal delivery [59410] and delivery by cesarean section [59500]; cataract removal [66984]; hysterectomy [58150]; and upper gastrointestinal endoscopy [43235].) Medicaid fees for state fiscal year 1989 were drawn from the Physician Payment Review Commission survey of state Medicaid programs. Estimated Medicare Fee Schedule fees for those services were based on a simulation of Medicare Fee Schedule payments for 1988. The conversion factor for the Medicare Fee Schedule is assumed to be budget neutral to Medicare allowed charges for 1988 minus 6.5%. The reduction of 6.5% reflects the HCFA decision to include an adjustment for volume responses in its implementation of the Medicare Fee Schedule.[29]

The index for each individual state is a weighted mean of the fee ratios. The weights were determined by the percentage of Medicaid physician expenditures attributable to all possible service codes in each family of services. These percentages were calculated from the HCFA Medicaid Statistical Information System for 1989.

[a]Assumes no change in the volume of services provided by physicians in response to fee changes.

the first order effect of adopting the Medicare Fee Schedule, assuming that increased fees have no effect on the volume of services provided.

The estimates assume that states with average Medicaid fees above those of the Medicare Fee Schedule will not decrease their fees to Medicare Fee Schedule levels. If they do so, the total change will be somewhat lower than estimated. Changes in office visit expenditures were estimated by including only office visit fees in the index of Medicare Fee Schedule to Medicaid fees and applying this ratio to the expenditures attributable to office visits. (The estimates assume that approximately 30% of expenditures are attributable to office visits. This estimate is based on data from the Medicaid Statistical Information System for 1989.)

Dually eligible beneficiaries. Projected total Medicare Fee Schedule expenditures for dually eligible beneficiaries were calculated in two ways. For states that pay the full coinsurance, the percentage change in Medicare expenditures under the Medicare Fee Schedule relative to Medicare allowed charges was simulated and multiplied by 1992 expenditures for the dually eligible beneficiaries. Second, for states that do not pay the full Medicare coinsurance, the fee index used for the nondually eligible beneficiaries was multiplied by current expenditures.

The estimates of changes in expenditures assume that all states would be required to pay the 20% copayment for dual eligible beneficiaries so that services for all Medicaid beneficiaries are paid at the Medicare Fee Schedule rate. Since state Medicaid programs' policies for this population follow Medicare's, both increases and decreases in payments are included in the expenditure estimates for this population.

Setting Medicaid Fees at Medicare Fee Schedule Levels

Setting Medicaid fees at Medicare Fee Schedule levels would increase total Medicaid physician service expenditures for current service volumes from $6.71 billion to $9.93 billion (Table 1). This additional $3.23 billion would increase total Medicaid expenditures (all services including physicians, hospitals, and long-term care) by about 3%. Under the current matching formula, the state share would be approximately $1.36 billion, and the federal share would be an estimated $1.87 billion.

The cost of raising Medicaid physician fees to Medicare Fee Schedule levels would vary among states because of current differences in Medicaid fee levels and use across states. Assuming no change in the volume of services, Medicaid physician expenditures in Alaska, Arkansas, Georgia, Indiana, Nebraska, and Nevada would experience little change, while expenditures in New York, New Jersey, and West Virginia would increase dramatically. Under this op-

tion, about 18% of the total growth in Medicaid physician expenditures would occur in New York.

The state shares of these increased expenditures would also vary because of differences in the current Medicaid matching formula (Table 2). For example, while Illinois and Mississippi would experience comparable percentage increases in expenditures (83%), Illinois would pay about 50% of the cost of its growth in physician expenditures and Mississippi would pay only about 20%.

Raising Medicaid fees to Medicare levels may be difficult to achieve in the short term. Even at current fee levels, states are already straining under the weight of growing Medicaid expenditures. In view of these financial pressures, policymakers may wish to consider more limited options for reforming Medicaid physician payment.

Increasing Fees for Selected Services

A second option is to raise fees for only certain types of services, such as office visits. A number of states have already implemented fee increases for primary care services and deliveries. This option targets increases in expenditures to those services for which access is most problematic.

Raising Medicaid fees for office visits is a particularly appealing policy option. Previous research has shown that low physician fees lead to increased care in hospital outpatient departments and emergency rooms. Raising office visit fees could encourage the substitution of office care for outpatient department and emergency room care in appropriate instances. Raising Medicaid office visit fees to Medicare Fee Schedule levels would increase physician expenditures by approximately $1.12 billion, or less than 1% of total Medicaid expenditures (see Tables 3 and 4). The federal share of this increase would be about $661 million; state expenditures would rise by approximately $460 million.

Again, the expenditure increases in individual states vary because of differences in current Medicaid fee levels, in the numbers of beneficiaries in each state, and in the use of office-based physician services. More than 25% of the total increase in expenditures due to this option would occur in California and New York. Expenditures for physician services in New York and West Virginia would increase by considerably more than 50%. Alaska, Arkansas, Massachusetts, and Nevada, which already have Medicaid office visit fees very near or above Medicare Fee Schedule levels, would incur negligible expenditure changes

[a]Assumes no change in the volume of services provided by physicians in response to fee changes.

proposal than if they raised all fees to the Medicare level. The reason is that their fees for evaluation and management services are lower relative to Medicare fees than are their procedural and surgical fees.

Other more limited options are available. For example, setting Medicaid fees at a percentage of Medicare Fee Schedule levels (e.g., 80%) would have the advantage of shifting the relative values for all services and increasing fees in many states and would be less costly to implement. The potential drawback to this option, however, is that the remaining gap between Medicaid fees and those of other payers may be substantial and could continue to discourage office-based physicians from providing services. Since primary care fees would increase relatively more than fees for other types of services, however, this policy might succeed in promoting greater willingness of primary care physicians to participate in Medicaid.

Impact of Changes in Volume and Site of Service

The previous sections have presented estimates of the first order effect of moving Medicaid fees to Medicare Fee Schedule levels. Total expenditures also will be influenced by changes in the volume of services provided, the site of primary care, and the mix of services.

The effect of changes in fee levels on total expenditures will be influenced by physicians' decisions regarding the volume of services provided to Medicaid beneficiaries. Recently, the Congressional Budget Office estimated that there would be a 50% increase in volume for Medicaid beneficiaries if Medicaid rates were raised to Medicare levels.[30] Work by Long and his colleagues suggests that a 10% increase in Medicaid physician fees for visits would increase the number of office visits by 3%.[19]

If the volume of office visits increases, the number of emergency room and outpatient hospital visits may decrease. Using the National Health Interview Survey for 1989, we estimated the proportion of emergency room or outpatient department visits for Medicaid beneficiaries that could be considered necessary. Following Sloan's research, visits for certain emergency conditions and on weekends were classified as necessary.[31] Slightly fewer than 25% of these visits appear to be necessary. Therefore, by improving access to office-based care and developing other policy changes such as primary care case management, there is the potential to save approximately 75% of Medicaid expenditures for outpatient and emergency room visits.

Expenditure changes due to increased volume would be partially offset by decreases in the use of emergency rooms (Table 5). If, as the Congressional Budget Office estimates, there would be a 50% increase in the volume of services

TABLE 5—Changes in Medicaid Physician Expenditures under Different Assumptions, 1992

Option	No Volume Response			With Volume and Site of Service Changes		
	Total Expenditure Change, $ Billions	Change in Physician Expenditures, %	Change in Total Expenditures, %	Total Expenditure Change, $ Billions	Change in Physician Expenditures, %	Change in Total Expenditures, %
All fees at Medicare levels	3.2	48	3	4.1	61	4
Visit fees at Medicare levels	1.1	17	1	−0.6	−10	−1

and potential savings in emergency room expenditures are realized, total Medicaid physician expenditures for the policy option of raising all Medicaid fees to Medicare levels would be $4.1 billion (or a 4% increase in total Medicaid expenditures). Under the option of raising physician visit fees only, there would be an overall decrease in expenditures. While it is doubtful that all expenditures from unnecessary emergency room care could be eliminated, there would be additional savings not included in these estimates because beneficiaries are less likely to use inpatient care when the original site of care is a physician's office. Medicaid expenditures for inpatient hospital services would probably decrease with the shift in the site of visits.[25,26]

Discussion

The available empirical evidence suggests that Medicaid physician payment policy affects the medical care that beneficiaries receive, often creating incentives that drive Medicaid patients away from physicians' offices to hospital outpatient departments or emergency rooms. Changing the payment levels for physicians' services could alter these incentives and make physician office care more available to Medicaid beneficiaries. The path that Medicare policy has followed—paying physicians for services based on a resource-based relative value scale—has potential usefulness for the Medicaid program. Medicaid payments based on the Medicare Fee Schedule could realign the relative values of Medicaid physician payments and raise these payments.

These reforms could be costly to institute, however. Although there would be a small increase in total national Medicaid expenditures, the increased costs to states would vary tremendously because of current differences in Medicaid programs among the states. Physician expenditures in a few states could double.

Strategies such as setting Medicaid fees at a percentage of Medicare Fee Schedule payments or adopting the fee schedule for certain types of services could be used to increase access to care at lower cost. These more limited approaches could be used to target increased expenditures to services for which the access problems are the most severe.

These options alone, however, may not improve access where it is most needed. In some locations, such as inner-city and rural areas, the present supply of physicians is too small to provide needed services. While it might be possible to raise fee levels enough to make some physicians willing to locate in underserved areas and to treat Medicaid patients, other factors may limit the magnitude of this response.[31] These factors include cultural and language differences, characteristics of these areas, and physicians' perceptions that Medicaid patients tend to have more serious medical problems, miss more appointments, and are less compliant than other patients. Some physicians are also wary that being labeled as a "Medicaid physician" may prompt other patients to seek care elsewhere. □

Submissions Invited for Public Health Policy Forum

The Journal department "Public Health Policy Form" is intended to present divergent views on important public health policy issues in a more extensive format than the Journal usually allows. Three kinds of material appear in the Forum: articles, not exceeding 4500 words; commentaries, not exceeding 2500 words; and editorials. Customarily, commentaries and editorials are solicited by the Journal's Contributing Editor or Editor. Articles for the Forum are selected from those submitted generally to the Journal or specifically to the Forum. In general, peer review is sought.

Those wishing to submit articles directly to the Public Health Policy Forum should send them to the Journal office as follows:

George A. Silver, MD, MPH
Contributing Editor, *AJPH* Public Health Policy Forum
1015 Fifteenth Street, NW
Washington, DC 20005

Please send five copies of the manuscript and follow the Journal's guidelines, "What *AJPH* Authors Should Know," printed in each issue of the Journal.

The scholarly merit and the scientific accuracy of all submissions are considered. Additional criteria are relevance to an important policy issue, timeliness, and clarity and coherence of the policy argument. Brevity also helps considerably.

Homicide, Handguns, and the Crime Gun Hypothesis: Firearms Used in Fatal Shootings of Law Enforcement Officers, 1980 to 1989

Garen J. Wintemute, MD, MPH

ABSTRACT

Objectives. Many policies seeking to limit handgun violence rest on the largely untested "crime gun hypothesis," which holds that subclasses of handguns differ in their risk for use in violent crime. This study tests that hypothesis for handguns used in homicides of law enforcement officers and describes the population of homicide-involved handguns.

Methods. A cross-sectional study was done of civilian (criminal) handguns used in homicides of law enforcement officers from 1980 to 1989. Life tables were generated for each year's cohort of new handguns to estimate gun-years at risk, analogous to person-years, for rate and relative risk calculations.

Results. Four hundred thirty-five deaths involved 428 civilian handguns. Revolvers were at greater risk than pistols. For both, risk was lowest for .22-caliber handguns. Risk was greatest for .32-caliber pistols and .38-caliber revolvers. Forty-six percent of handguns had a barrel length of 3 in or less.

Conclusions. Subclasses of handguns differ substantially in their risk for use in fatal shootings of law enforcement officers. Such epidemiological data may be useful in formulating efforts to prevent these and similar instances of firearm violence. (*Am J Public Health.* 1994; 84:561–564)

Introduction

Regulatory efforts to prevent firearm violence often address specified classes of firearms. In the 1960s, the proliferation and criminal use of inexpensive, small-caliber handguns—Saturday Night Specials—led to severe restrictions on their importation under the Gun Control Act of 1968. In 1990, similar concerns regarding certain high-capacity semiautomatic weapons led to an administrative ban on their importation.

Such policies are grounded in a belief in the validity of the "crime gun hypothesis," which holds that all firearms are not at equal risk for use in a violent crime. This hypothesis has clearly been validated in the case of handguns generally, as compared with rifles and shotguns. While handguns constitute perhaps 40% of firearms produced in the United States in the past 2 decades, they account for 80% of all violent crimes involving firearms.[1]

The crime gun hypothesis has not been rigorously tested for the various classes of handguns because the necessary data have been lacking. While information on the characteristics of handguns released into circulation—as approximated by data on handguns manufactured or imported—is compiled only on a national basis, no nationally based data on handguns actually used in violent crimes have been available.

Previous explorations of this issue have yielded conflicting results. In the 1970s, half or more of all handguns confiscated by police agencies were of small caliber, had short barrels, or both.[2,3] Later critics noted that many of these "crime guns" had not actually been used in violent crime; some had no criminal associations at all.[4,5] In contrast, two surveys of convicted felons suggested that such criminals most often use high-quality, high-caliber handguns, particularly if they rely heavily on firearms in committing crimes.[6,7] Both studies were based entirely on self-report; new data on handguns actually confiscated from violent career felons at the time of their arrest show that both large- and small-caliber handguns are in common use by this group.[8] None of these studies estimated the actual or relative risk of different classes of handguns being used in crime.

The present study attempts to provide a more exact, albeit narrowly focused test of the crime gun hypothesis. Its subjects are the civilian handguns used in homicides of law enforcement officers in the United States from 1980 to 1989; this is the only instance in which detailed, nationally based data on firearms actually used in violent crime have been compiled. Such data are compatible with the nationally based information used to estimate handgun availability.

I estimate absolute and relative risks for involvement in these fatal shootings by handgun type (revolver or pistol) and caliber, the two characteristics for which availability data are collected, and I test two hypotheses: (1) that risk will be positively associated with handgun caliber; and (2) that risk will be higher for pistols than for

Editor's Note. See related editorial by Kaufer Christoffel (p 539) and annotation by Kellermann (p 541) in this issue.

revolvers. As for the first hypothesis, small area studies have found an association between larger caliber and higher case-fatality rates for assaultive violence involving handgun use.[2,4,9] As for the second, pistols have been reported anecdotally to be used with increasing frequency in violent crime, including the crime at issue here. Pistols carry more ammunition than revolvers do, typically between 9 and 16 rounds, and automatically bring a new round into firing position each time a round is discharged. Revolvers generally carry only 5 to 6 rounds, and many must be recocked manually each time the gun is to be fired.

Finally, I describe this population of homicide-involved handguns with regard to characteristics for which the existing data do not permit an estimation of risk.

Methods

Data Sources

Data on all firearm homicides of law enforcement officers in the United States from 1980 to 1989 were provided by the Uniform Crime Reporting Program of the Federal Bureau of Investigation (FBI). Information in the dataset is collected from local law enforcement agencies, FBI field divisions, and the agency's Bureau of Justice Assistance. Reports are cross-checked for validity and completeness.[10]

Data on new handgun availability were provided by the Bureau of Alcohol, Tobacco and Firearms, which collects such information from manufacturers and importers by handgun type and caliber, but not by barrel length or ammunition capacity. Information on handguns manufactured in the United States was first collected in 1973; comparable data on imported handguns were not collected until 1988. Data on exported handguns, which account for about 10% of domestic manufactures, do not exist.

Data Management

Not all records were complete, presumably owing to failure to obtain the weapon involved. Missing information was sought from manufacturer catalogs, lay publications, and scholarly manuals of firearms identification.[11,12] Data were added for 52 handguns when this supplemental review established that only one value for the missing variable was possible. Residual frequencies for missing data were greater than 5% for gun type (7%), manufacturer (25%), and barrel length (34%).

Seven shootings were reported in which more than one law enforcement officer appeared to have been killed with the same handgun. Only one observation was retained.

Analysis

Numerators for rate and relative risk estimates were taken directly from the FBI data. Because imported handguns were missing from the denominator dataset until 1988, homicides involving such weapons were excluded until that year.

Denominators were expressed as gun-years at risk, an analog to person-years, for each gun type and caliber. Gun-years at risk accumulated from 1980 to 1989 were estimated for each annual cohort of new handguns produced from 1973 through 1989, specific to handgun type and caliber, by generating demographic life tables.[13,14]

The size of each annual cohort at inception was approximated by the number of handguns manufactured for 1973 to 1987, and by the number of handguns manufactured plus the number of handguns imported for 1988 to 1989. The annual attrition rate was also estimated, as nationally based data on the persistence of handguns in circulation are not available. Police handgun confiscation studies from the 1970s found that approximately half of these weapons had been manufactured within 3 to 5 years of confiscation.[2,3,15] The life tables were therefore first constructed under the assumption that the annual rate of attrition was 0.10 for each gun type and caliber. Rates were calculated under this model.

To estimate the sensitivity of the results to variations in the survival model, gun-years at risk for each annual cohort of new handguns were also calculated for rates of attrition of 0.05 and 0.20. Confidence intervals (CIs) for relative risk (RR) estimates were derived by the method of Katz[16] using Confidence Interval Analysis software.[17]

Results

There were 735 firearm homicides of law enforcement officers from 1980 to 1989, of which 435 (59%) were committed with the 428 civilian (criminal) handguns that are the subjects of the present study. Of these guns, 296 (69%) were revolvers, 104 (24%) were pistols, and 28 (7%) were of unknown type. Most handguns (53%) were of medium caliber (.38 or 9 mm). Small-caliber (.22 to .32) handguns accounted for 20% of all weapons.

Short-barreled handguns predominated among both pistols and revolvers; of 288 guns for which information was available, 134 (47%) had a barrel length of 3 in or less. Such weapons accounted for 78% of all .22- to .32-caliber handguns and 54% of all .38-caliber or 9-mm handguns.

Firearms manufacturers based in the United States accounted for 82% of the 322 handguns for which a manufacturer was identified; the four most frequently identified firms produced 59% of these weapons.

Revolvers were at greater risk than pistols (RR = 1.40; 95% CI = 1.10, 1.77). For pistols and revolvers alike, handgun caliber was associated with large differences in their rates of use in these events (Figure 1). Rates were lowest for .22-caliber handguns. Among pistols, .32-caliber weapons were at greatest risk (RR = 15.3; 95% CI = 5.56, 41.9), but these relatively uncommon weapons accounted for only 9% of all homicide-involved pistols. Nearly half (49%) of all pistols were of .38 or 9-mm caliber (RR = 7.28; 95% CI = 3.65, 14.5). Among revolvers, risk was highest for .38-caliber weapons (RR = 9.02; 95% CI = 5.31, 15.3). This group accounted for 57% of all revolvers of known caliber and 42% of all handguns for which both gun type and caliber were known. Rates for the largest caliber handguns were lower than those for weapons of intermediate caliber.

The relative risk estimates were minimally sensitive to fourfold variations in the hypothesized rate at which handguns disappear from circulation. The ranking of handgun types and calibers by their relative risk for use in these events was not affected (Table 1).

Discussion

The crime gun hypothesis appears to be valid for the specific crime of homicide of a law enforcement officer. Among commonly available handguns, differences in risk for use in these fatal shootings are associated with specific design characteristics. Some of these differences are substantial; all are only modestly affected by large variations in

the hypothesized rate at which handguns are removed from circulation.

The finding that small-caliber handguns are at relatively low risk was expected. Handguns used in homicides are substantially more likely than handguns used in nonfatal assaults to be of large caliber.[2,4,12] The finding of low risk at low caliber may be specific to homicide, reflecting the lower lethality of these handguns.

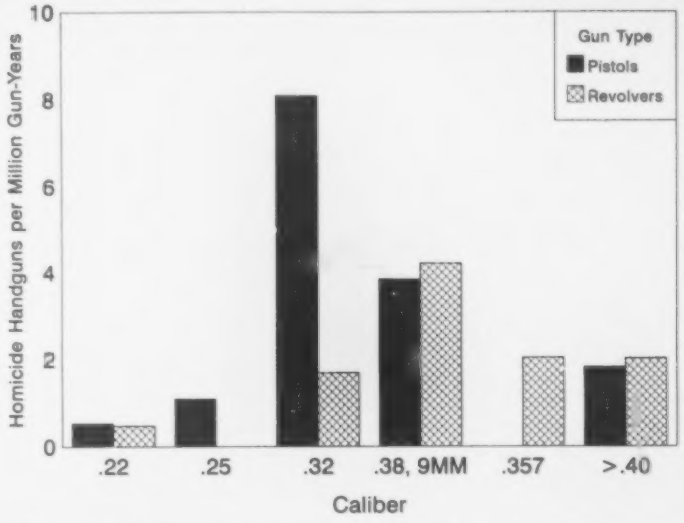
The relatively low rates among the highest caliber weapons were not expected but may be partly explained by price elasticity in handgun acquisition decisions by criminal users. High-caliber handguns are often substantially more expensive than low-caliber weapons—by as much as 50% or more at retail list prices and perhaps more at street pricing.

The predominance of handguns with short barrels—a key factor in weapon concealability—is consistent with earlier reports. Police studies have consistently found a high frequency of short-barreled weapons among confiscated handguns.[2,3,4] Convicted felons report that concealability was one of the chief factors influencing their handgun selection.[7] A Florida survey of convicted felons and gun owners in the general population found that the latter group was far less likely to report owning a handgun with a barrel length of 3 in or less (odds ratio = 0.22; 95% CI = 0.15, 0.34; this author's calculation).[6]

The quality of the data available for this study raises several caveats. The FBI data frequently omit handgun manufacturer and barrel length. However, there is no a priori reason to expect that values for these variables are related to the frequency of missing data, and no bias is expected. The Bureau of Alcohol, Tobacco and Firearms data describing handguns in the United States do not include characteristics such as barrel length; the association between these characteristics and risk for use in firearm violence cannot be quantified.

A direct measure of guns sold at retail does not exist. Over a brief period of time, fluctuations in the inventory of unsold handguns could result in a significant difference between the number of handguns available for sale and the number actually sold (or stolen) and entering the population at risk for criminal use. However, it is unlikely that such a difference would persist across the 17-year period used here.

Similarly, no nationally based data exist on the persistence of handguns in circulation. The robustness of the relative risk estimates across widely varying hypothesized rates of attrition suggests that a reasonable assessment of relative risk, if not of absolute risk, can be made without this information. However, the results depend on the design of the model used to generate them. We have assumed that all subclasses of handguns are lost from circulation at the same rate. This may not be the case. In particular, the guns most at risk for use in violent crime may also be most at risk for confiscation and for abandonment. If this is true, then gun-years for these weapons have been overestimated and the relative risks presented here are artificially low.



Note: Homicide handguns per million gun-years is defined as the number of guns used in homicides divided by the estimated total number of handguns times their duration in circulation (in millions of years). See the Methods section.

FIGURE 1—Rates of handgun use in homicides of law enforcement officers, by caliber and gun type, United States, 1980 to 1989.

.38/9 mm	7.36	3.69, 14.7	7.28	3.65, 14.5	7.15	3.58, 14.3
>.40	3.45	1.51, 7.87	3.45	1.51, 7.85	3.45	1.51, 7.86

Other limitations arise from the absence of more generally applicable information. First, handguns used in homicides of law enforcement officers may not be representative of all handguns used in homicides. While .22- to .32-caliber handguns made up 20% of the weapons in this series, they constituted 33% to 52% of homicide-involved handguns in four major cities in studies conducted during the 1970s.[2,9] The creation of a firearm fatality reporting system has recently been recommended[18] and could be implemented with relative ease.

Second, the handguns most at risk for use in homicide may be quite different from those most at risk for use in nonfatal assaultive violence. To begin to address this issue, it might be feasible to acquire information on firearms used in nonfatal shootings of law enforcement officers. From 1980 through 1989, 29 339 assaults on law enforcement officers with firearms were reported, of which 6496 (22%) involved injury.[10] The Department of Justice, the Consumer Product Safety Commission, and the Centers for Disease Control and Prevention have also explored adding firearm injuries to the existing National Electronic Injury Surveillance System.[19,20]

Concerns about generalizability do not pertain to the implications of these findings for law enforcement personnel themselves. This group is at high risk for occupational homicide, with rates of 20 to 25 homicides per 100 000 officers per year.[21,22] Most such deaths involve firearms; nearly half result from wounds to the front upper torso, and nearly 60% occur when the shooter and the victim officer are separated by 5 ft or less.[10] Our data show that 9-mm or .38-caliber handguns are most commonly involved. Law enforcement policymakers should consider requiring the use of soft "body armor," which provides protection against such weapons at close range.

Law enforcement officers also need enhanced safeguards against assaults using their own firearms. During 1980 to 1989, 21% of officers killed with a handgun were shot with their own service weapon, and others were killed with a handgun taken from a fellow officer. Law enforcement agencies often avoid purchasing handguns with trigger arresters or other safety devices in order to minimize the time delay to firing when the officer is in control of his or her own weapon.[23,24] These data suggest that attention should be given to modifications of firearm design that would not impede the officer's ability to use the weapon but would make it more difficult for others to do so.

The question of whether broad limitations on the availability of handguns would reduce the incidence of these events is outside the scope of this study. My data do indicate, however, that restrictions limited to imported firearms—a characteristic of much of American firearms policy—will not be effective. □

Acknowledgments

The author is grateful to Mr Thomas Wilson of the FBI's Uniform Crime Reporting Program and to Mr Jack Killorin, Chief, Public Affairs Branch, Bureau of Alcohol, Tobacco and Firearms, for furnishing the data used in this study. Dr Jay Beaumont, Prof Stephen Teret, and Ms Mona Wright provided helpful comments on earlier drafts. In addition, Ms Wright and Ms Barbara Claire provided expert technical assistance.

The Prevalence and Correlates of Fear of Falling in Elderly Persons Living in the Community

ABSTRACT

Objectives. Fear of falling has been recognized as a potentially debilitating consequence of falling in elderly persons. However, the prevalence and the correlates of this fear are unknown.

Methods. Prevalence of fear of falling was calculated from the 1-year follow-up of an age- and gender-stratified random sample of community-dwelling elderly persons. Cross-sectional associations of fear of falling with quality of life, frailty, and falling were assessed.

Results. The prevalence of fear increased with age and was greater in women. After adjustment for age and gender, being moderately fearful of falling was associated with decreased satisfaction with life, increased frailty and depressed mood, and recent experience with falls. Being very fearful of falling was associated with all of the above plus decreased mobility and social activities.

Conclusions. Fear of falling is common in elderly persons and is associated with decreased quality of life, increased frailty, and recent experience with falls. (*Am J Public Health.* 1994;84:565–570)

Cynthia L. Arfken, PhD, Helen W. Lach, MSN, Stanley J. Birge, MD, and J. Philip Miller, AB

Introduction

Falling in elderly persons can lead to disability, hospitalizations, and premature death.[1,2] It may also result in a psychological trauma termed fear of falling.[3,4] Such fear may lead to staying home or other self-restriction of activities with debilitating physical consequences. Although fear of falling is recognized as potentially having both psychological and physical consequences, few studies have examined this fear.[5–11] Moreover, these studies have been limited by use of select samples: small groups of patients,[5,6] elderly persons living in housing units or retirement homes,[7–10] or volunteers.[11] Although these studies have reported isolated associations with factors such as decrease in mobility or poor balance, the association of fear of falling with decreased quality of life and increased frailty is unknown. Likewise, the prevalence of fear of falling in a random sample of community-dwelling elderly persons is unknown.

In addition to reporting associations with factors such as mobility or balance, two studies have examined the association of fear of falling with the prior falling experience of subjects.[7,8] One study examined prevalence of fear of falling in subjects with one or more falls in the prior year,[7] and the other examined restriction of activities after a noninjurious fall.[8] However, development of fear of falling may also be related to other measures previously used in research on geriatric falls: circumstances of the fall,[12,13] recurrent falls,[14–17] or severity of resulting injury.[18]

The current study was developed to examine prevalence of fear of falling and its association with measures of falling, quality of life, and frailty.

Methods

The current study was added at the 1-year follow-up of a cohort study of community-dwelling elderly persons. The primary purpose of the parent study was to design a simple screening tool to be used in the physician's office for predicting falls in elderly persons.

From the St. Louis OASIS (Older Adult Service and Information System) membership of 16 632 older adults, a gender- and age-stratified random sample of 1358 community-dwelling elderly persons was recruited (66% participation rate) to provide approximately equal numbers in four age groups: 65 through 69 years, 70 through 74 years, 75 through 79 years, and 80 years or older, with a ratio of 2 women to 1 man in each age group. Subjects from each stratum entered the study evenly over the course of a year with no excess of difficult-to-recruit subjects in the later months. To avoid subjects with severe cognitive impairment, individuals with 12 or more errors on the Mini-Mental State Examination[19] were excluded from the study (n = 15).

The fall surveillance procedure initiated after recruitment consisted of

TABLE 1—The Prevalence (%) of Fear of Falling, by Gender and Age Groups

	Men				Women			
	66–70 y (n = 87)	71–75 y (n = 82)	76–80 y (n = 66)	81+y (n = 58)	66–70 y (n = 156)	71–75 y (n = 158)	76–80 y (n = 137)	81+y (n = 146)
No fear	86	85	86	79	79	63	60	55
Moderately fearful	10	15	12	16	15	26	28	34
Very fearful	3	0	2	5	6	11	12	11

subjects reporting falls to a hot line immediately after the fall plus monthly postcards to document any falls they had sustained, whether or not they had reported the falls by phone. Each month the investigators called all subjects who did not return postcards to verify that the subject was still in the study and solicit information about any unreported falls. After a report of a fall from the hot line, postcard, or phone, one of two trained gerontological nurses conducted a brief telephone interview with the subject to verify that a fall had occurred and the circumstances and outcome of it.[12]

One year after initial recruitment, 890 subjects received a structured in-home reassessment. Reasons for loss to follow-up included death (n = 30), moving (n = 2), refusal (n = 125), budgetary cuts (subjects recruited in the last 2 months were dropped [n = 290]), and incomplete information (incomplete interview [n = 33], telephone interview only [n = 69]). Those lost to follow-up were, on average, older than those for whom follow-up information was obtained. No other differences were found between those who were followed-up and those who were lost to follow-up. The final sample was predominately female (67%), White (93%), and educated (62% finished high school). Overall, 78% rated their health as excellent or good.

The in-home reassessment was conducted by lay interviewers and included demographic characteristics, health status, activity level, satisfaction with life, depressed mood, and a brief physical assessment. To measure the extent of fear of falling, the following question was asked of everyone: "At the present time, are you very fearful, somewhat fearful or not fearful that you may fall (again)?"

Quality-of-Life Measures

Quality-of-life measures covered mobility and social activities, satisfaction with life, and depressed mood. The mobility and social activities measures consisted of three questions on frequency of leaving the building or residence but not the yard, frequency of leaving the building and yard, and frequency of participating in social activities (i.e., "religious or club meeting, visiting friends or family, eating with other people, going to a social event or having friends in"). These three measures were dichotomized before this analysis by using a cutpoint of three times per week. These cutpoints were chosen for ease of interpretation and the criterion that at least 5% of the sample be in one of the categories. Satisfaction with life was dichotomized by using the contrast of "very" to "somewhat" or "not at all" satisfied. Depressed mood was analyzed with the Geriatric Depression Scale,[20] a 30-item scale where a higher score indicates a more depressed mood. Both the total score and a dichotomous score were used. The latter score used the recommended cutoff of 11 as suggestive of depression.[21]

Frailty Measures

Frailty measures covered episode of near fall, inability to walk 10 blocks, requiring assistance to climb stairs, poor vision limiting ambulation, use of assistive device to ambulate, general health status, and a balance score from the physical assessment. The balance assessment consisted of maintaining parallel, semitandem, and tandem stances for 10 seconds in each stance with eyes open and then with eyes closed. The balance score was computed as the number of stances correctly maintained (maximum = 6). This variable was dichotomized with a score of 4 or less suggesting impaired balance, a decision based on clinical interpretation.

Falls Measures

Measures of experience with falls covered a single fall, recurrent falls (two or more), a fall other than a trip or slip over a recognized hazard, a fall resulting in injury, a fall requiring medical treatment, a fall resulting in a fracture, or a fall with a delay in getting up (more than 1 minute). These falls must have occurred after recruitment and before the in-home reassessment.

Analysis

Statistical analysis consisted of first testing for differences in quality of life, frailty, and falling by the extent of fear of falling with the chi-square test for categorical variables and the Kruskal-Wallis Rank Test for the continuous score on the Geriatric Depression Scale. Then the associations of the categorical variables with fear of falling were summarized as odds ratios (ORs) obtained from multivariate logistic regressions with gender, age (as a continuous variable), and gender and age interaction terms. The corresponding large-sample 95% confidence intervals were also calculated.

Fear of falling in the logistic regressions was analyzed both as an ordinal variable with three levels and as a dichotomous variable. For the latter, we used models contrasting "moderately fearful" with "no fear" and models contrasting "very fearful" with "no fear." Logistic regression was also used to test the association of fear of falling as an ordinal variable with age and gender. Factors independently associated with fear of falling as an ordinal variable were identified by using logistic regression with stepwise selection after verifying that the proportional odds assumption was met. All analyses were conducted with SAS.[22]

To assess the effect of the chosen cutpoints, we used probability plots.[23] From these plots, the associations of mobility and social activities with fear of falling appeared monotonic. For balance, the associations would be maximized at cutpoints of 3 to 4.

Results

The majority of the sample (71%) expressed no fear of falling, whereas 9% reported they were very fearful of falling. Table 1 presents the fear-of-falling prevalences by gender and age groups. Women were more likely than men to express some fear of falling (35% vs 15%; $P < .0001$). However, fear of falling increased with age for both genders. In women, 21% of the youngest group (66–70 years) reported some fear of falling. This prevalence increased to 45% in the oldest age group (81+ years). In men, 14% of the youngest group reported some fear of falling, vs 21% of the oldest group.

Those who were very fearful of falling were most likely to have a decreased quality of life (Table 2). Almost half (48%) of those persons who were very fearful of falling stated that they were somewhat or not at all satisfied with life. In addition, 25% had scores suggesting depression. The continuous score on the Geriatric Depression Scale also differed by the extent of fear of falling: those who were very fearful had a mean score of 8.3 (SD = 4.8); those who were moderately fearful had a mean score of 7.2 (SD = 4.6); and those who were not fearful had a mean score of 4.8 (SD = 3.6) ($P < .0001$).

After gender and age adjustment, those who were very fearful of falling still had an elevated risk for worse quality of life on every measure (Table 3). This elevated risk was most pronounced for infrequently leaving the building (OR = 6.05). In contrast, those who were moderately fearful of falling did not have elevated risks for decreased mobility and social activities. However, they did have elevated risk for dissatisfaction with life (OR = 1.82) and depressed mood (OR = 2.20).

Those who were very fearful of falling were most likely to be frail or have falls on all measures (Table 4). Almost all (85%) of those who were very fearful of falling had impaired balance. The percentages of subjects with impaired balance did not materially change after excluding those who refused to perform the balance assessment (47% of subjects who had no fear, 66% who were moderately fearful, and 79% who were very fearful). Although the interviewers were instructed to stand near the subject in case assistance was needed, subjects fearful of falling may still have been fearful of trying the more difficult stances.

TABLE 2—The Prevalence (%) of Decreased Quality of Life, by Subject's Level of Fear of Falling

Quality-of-Life Measure	Subject's Level of Fear: No Fear (n = 633)	Moderately Fearful (n = 190)	Very Fearful (n = 67)	P[a]

TABLE 3—Associations of Fear of Falling with Quality-of-Life Measures

Quality-of-Life Measure	Moderately Fearful: Not Fearful OR	Moderately Fearful: Not Fearful 95% CI	Very Fearful: Not Fearful OR	Very Fearful: Not Fearful 95% CI
Infrequently leave building but not yard[a]	1.07	0.41, 2.80	6.05	2.46, 14.90
Infrequently leave building and yard[a]	1.00	0.54, 1.83	2.94	1.45, 5.96
Infrequent social activities[a]	0.90	0.62, 1.31	1.75	1.03, 2.97
Less than very satisfied with life[b]	1.82	1.26, 2.63	3.08	1.81, 5.25
Depressed mood[c]	2.20	1.36, 3.57	3.18	1.68, 6.04

Note. Odds ratios (ORs) and confidence intervals (CIs) were obtained from logistic regression models including gender, age, and gender and age interaction term.
[a]Less than three times per week.
[b]"Somewhat" or "not at all" vs "very" satisfied.
[c]Score of 11 or more on Geriatric Depression Scale.

Of those subjects who were very fearful of falling, 9% had had a fracture in the prior year compared with less than 0.5% of those with no fear and 2% of those with moderate fear. The reported fractures were ankle, hip, and leg (three subjects with no fear); pelvis, ribs, wrist, and shoulder (four subjects with moderate fear); and three hips, two shoulders, and one face (six subjects who were very fearful). Delay in getting up after a fall was similarly uncommon but more frequent in those very fearful of falling. Although this variable was dichotomized at greater than 1 minute, one subject lay on the ground over 1 hour after falling.

Almost all (91%) of those who were very fearful of falling reported at least one of the characteristics associated with frailty, in contrast to 59% of those with no fear of falling.

After gender and age adjustment, those who were very fearful of falling still had an elevated risk for both frailty and experience with falls on every measure (Table 5). This risk was most pronounced for fractures (OR = 28.16) and using an assistive device to ambulate (OR = 9.87).

To evaluate the independence of these associations, we conducted analysis using stepwise logistic regression models. Five variables were indepen dently associated with extent of fear of falling (Table 6). These factors were a fall resulting in a fracture (OR = 6.65),

TABLE 4—The Prevalence (%) of Frailty and Recent Experience with Falls, by Subject's Level of Fear of Falling

requiring assistance to climb stairs (OR = 4.31), vision limiting ambulation (OR = 3.72), fair or poor self-rated health (OR = 2.89), and a fall besides a slip or trip (OR = 2.71).

Discussion

Fear of falling was common in this sample of relatively well community-dwelling elderly persons and comparable to that reported for a retirement center.[9] The associations of fear of falling with frailty and falls suggest a consistent trend toward a greater degree of association of these variables with a greater degree of fear. Although other unmeasured factors (such as personality and social factors) may play a role, the factors examined here had strong associations with fear of falling even after adjustment for gender and age. Moreover, in multivariate analysis, the extent of fear of falling was independently associated with experience with falls (fractures and falls not caused by a trip or slip) and frailty (problem climbing stairs, vision limiting ambulation, and poor health).

The strong and consistent association of fear of falling with decreased quality of life highlights the public health relevance. Given the design constraints, we cannot say whether the decreased quality of life preceded, accompanied, or followed the development of fear of falling. This caveat is also true for frailty and experience with falls. For this reason, we did not attempt more complex analyses assuming directionality (e.g., frailty leading to falling leading to

depressed mood leading to fear of falling). Asking about fear of falling at initial recruitment and at the reassessment would have been preferable both for determining generalizability and for predicting the development of fear of falling. However, the supposition that decreased quality of life follows a fall is supported by a case–control study[8] on noninjurious falls in retirement homes that found greater restriction of activities or death 180 days later.

Relying on the response to one question to determine the extent of fear of falling is a potential concern. Other researchers have defined fear of falling as curtailment of activities,[8] curtailment of activities because of fear of falling,[7] and self-efficacy in avoiding falls while performing specific activities.[11] These diverse definitions have advantages and disadvantages. Curtailment of activities has been criticized for lack of reliability.[11] Self-efficacy, while theoretically promising in being sensitive to change, suffers from difficulty in administration (i.e., subjects have to understand and estimate the extent of their confidence in their ability to avoid falls while performing a select list of activities). The approach we used is a step toward understanding this phenomenon and has been used by others.[9,10]

Three additional concerns are the low response rate for the parent study, the reduced cohort for the present study, and the reliance on self-report for frailty measures. The response rate, although similar to that reported by other investigators in gerontological research,[24] is troublesome because it is plausible that those who were fearful of falling might have been more likely than others to refuse to participate. This bias would have the effect of underestimating the prevalence of fear of falling. We interviewed subjects in their homes to minimize missing those subjects who were afraid to leave their home, but we may still have underestimated the prevalence of fear of falling.

Addressing the second concern, the cohort for the current study was 34% smaller than the recruited cohort, which limits generalizability. However, the majority of this decline (62%) was initiated by the investigators (i.e., terminating surveillance on those recruited in the last 2 months of the study). Analysis confirmed that the persons in the reduced cohort did not differ from those who were not followed, except that those who were not followed were older. This analysis suggests that we may have underestimated the prevalence of fear of falling in the original cohort and also limited our power to detect associations in the older age group.

The third concern is the reliance on self-report. The resulting associations between self-report of frailty and self-report of fear have competing interpretations. The subjects could have a rational fear of falling in response to their frailty. Alternatively, the subjects could be fearful and view themselves as more frail than they are. Although we included a performance-based measure of frailty (balance), the performance may be biased by fear of trying.[10]

One of the strengths of this study was that we used prospective documentation of falling with telephone verification for all the falls reported.[25] Therefore, we avoided biases due to potential differential recall of past falls. However, we did not assess falls occurring in the remote past or the impact of falls experienced by others, both of which could influence the development of fear of falling. For example, someone hearing of a traumatic fall leading to institutionalization may become fearful of falling. This analysis indicated that half of those who were very fearful of falling had not fallen in the prior 12 months. We don't know how long they had been fearful or how the fear was triggered. A more extensive look at the fear of falling should incorporate these factors.

In conclusion, we found fear of falling to be common in a sample of community-dwelling elderly persons. The extent of the fear was associated with self-reported and performance-based measures of frailty and prior experience with falling. The observed associations of fear of falling with decreased quality of life and mobility confirm the need for effective interventions to prevent and limit the consequences of falls in elderly persons. □

Upcoming Centers for Disease Control and Prevention Conferences

Call for Abstracts on Chronic Disease Prevention

The Centers for Disease Control and Prevention (CDC) is issuing a call for abstracts for the Ninth National Conference on Chronic Disease Prevention and Control, to be held in Washington, DC, December 7 through 9, 1994. Topic areas include chronic disease epidemiology, interventions, and intervention assessment and evaluation. The deadline for submission is *May 18, 1994.* For more information, contact Jack Friel, NCCDPHP, CDC, 4770 Buford Hwy NE, Mailstop K-30, Atlanta, GA 30341-3724; tel (404) 488-5390; fax (404) 488-5974 or (404) 488-5962.

BRFSS Conference to Be Held

CDC will sponsor the 11th annual Behavioral Risk Factor Surveillance System (BRFSS) Conference at the Atlanta Hilton and Towers in Atlanta, Georgia, June 8 through 10, 1994. The agenda will include utilization of behavioral risk factor data, issues and opportunities related to the analysis of data, updates on computer-assisted telephone interviewing systems, and recommendations to be adopted from an evaluation of the BRFSS. State BRFSS program coordinators, survey contractors, behavioral scientists, statisticians, epidemiologists, and others involved in the collection, analysis, and utilization of behavioral risk factor data are invited to attend. There is no registration fee. Additional information is available from the Behavioral Risk Factor Surveillance Branch, National Center for Chronic Disease, CDC, 4770 Buford Hwy NE, Mailstop K-30, Atlanta, GA 30341-3724; tel (404) 488-5292.

Using Physician Correspondence and Postcard Reminders to Promote Mammography Use

Stephen H. Taplin, MD, MPH, Carolyn Anderman, MPH, Lou Grothaus, MS, Susan Curry, PhD, and Daniel Montano, PhD

ABSTRACT

Objectives. In a health maintenance organization that mails letters to women recommending that they schedule mammograms, we conducted a randomized trial to evaluate simple methods of increasing the use of screening mammography.

Methods. Using a 2 × 2 factorial design, we tested the effects of (1) mailing the recommendation letter from each woman's primary care physician rather than from the program director and (2) sending a subsequent reminder postcard.

Results. Sending a reminder postcard nearly doubled the odds that women would get mammograms within 1 year (participate). The letter from the woman's personal physician had no effect. Attending a clinic more than 45 minutes from the screening center, being a current smoker, or being in fair or poor health were negatively associated with subsequently obtaining a mammogram. The odds of participation doubled if women had had previous mammograms.

Conclusions. When preceded by written recommendations to schedule mammograms, reminder postcards effectively increased participation. Future randomized trials to promote use of screening mammography should compare interventions with a reminder condition. (*Am J Public Health.* 1994;84:571–574)

Introduction

Breast cancer mortality remained constant from 1973 through 1988, partly because of the underuse of mammography.[1–7] By 1990, only about one third of women reported having had more than one mammogram.[6,7]

Mailing recommendations directly to women offers a promising approach to increasing mammography use. Such recommendations increased the use of blood pressure checks, influenza vaccines, and cancer screening tests.[8–19] In a Swedish randomized trial of mammography, mailed recommendations resulted in 92% of the women in the study getting mammograms.[20,21] In the United States, 21% to 65% of women obtain mammograms after mailed recommendations.[8,11,12,16,17,22]

We undertook a randomized trial to test whether we could increase participation in an established screening program that routinely mails recommendations to women due for mammograms.[12,23,24] We tested two enhancements: (1) mailing the recommendation letter from each woman's primary care physician rather than from the program director and (2) sending a subsequent reminder postcard. We based the interventions on the Health Belief Model, which suggests that cues to action promote preventive care behavior.[25,26]

Methods

Setting

Group Health Cooperative of Puget Sound is a staff model health maintenance organization with over 375 000 enrollees and the full complement of health care services. Adult Group Health Cooperative members choose from among family physicians or internists who each care for 1600 to 1800 enrollees. The populations of both the Group Health Cooperative and Puget Sound have a higher proportion of Caucasians (91%) than national figures (83%).[27,28] The Cooperative has a greater proportion of enrollees with more than 15 years of education (Group Health Cooperative = 34%, Puget Sound = 24%, and United States = 16%). There are also slightly fewer Cooperative enrollees with incomes below $15 000 (in 1984 dollars: Group Health Cooperative = 20%, Puget Sound = 23%, United States = 24%) and above $50 000 (in 1984 dollars: Group Health Cooperative = 13%, Puget Sound = 19%, and United States = 18%).[27,28]

Screening Program

In 1985, the Group Health Cooperative initiated a Breast Cancer Screening Program for women age 40 years and older.[12,23,24] Eighty-seven percent of women age ≥40 years complete an enrollment questionnaire that elicits breast cancer risk factors, perceived health status, smoking history, and previous mammography use. Once they are

[b]BCSP = Breast Cancer Screening Program.

enrolled, an automated system sends letters to women due for mammograms. The letter is signed by the Breast Cancer Screening Program medical director, recommends scheduling a mammogram at one of three screening centers, and emphasizes the importance of the test.

Study Population and Design

We randomized women who were (1) age 50–79 years and had completed the questionnaire more than 1 year before randomization, (2) current Group Health Cooperative enrollees who had not been previously invited to a screening center, and (3) without a mammogram in the year before randomization. In order to have adequate numbers of women eligible for first invitations, we restricted the study to women who did not have a first-degree family history of breast cancer or more than one minor risk factor (early menarche, late menopause, second-degree family history of breast cancer).[24]

By making small changes in the Breast Cancer Screening Program correspondence, we tested the independent and combined effects of (1) having the recommendation letter come from the woman's physician rather than from the Breast Cancer Screening Program medical director (primary physician invitation) and (2) sending a reminder postcard to women 2 months after the recommendation letter (reminder postcard).

A sample of 1500 women was identified through the breast cancer program database, and these women were randomly allocated to four groups: (1) primary physician invitation (n = 329); (2) reminder postcard (n = 335); (3) primary physician invitation plus reminder postcard (n = 334); and (4) usual-care control group (n = 324). Subsequent to randomization, 11.5% of women were excluded from the study because they terminated Group Health Cooperative coverage (n = 34) or obtained a mammogram before being sent the recommendation letter (n = 135). Study data came exclusively from the program database and the risk factor questionnaire. All women were blinded to the study and received identical care to other women being invited at the same time.

Recommendation letters and reminder postcards were mailed directly to study women. When the primary care physician personally signed the letter, it also included a paragraph that emphasized the importance of the screening visit in the woman's overall health care. Reminder postcards were sent to all women in the appropriate study group without checking participation status beforehand.

Analysis

We compared baseline demographic characteristics, health status, screening history, and logistical barriers to participation among study groups. We dichotomized all characteristics (Table 1) and compared proportions among intervention populations using chi-square tests. We compared mean age and enrollment length using analysis of variance.

Using receipt of a mammogram within 12 months of the invitation letter (yes/no) as the dependent variable in a logistic regression model, we tested for the main effects of the primary physician letter, the reminder postcard, and the interaction of the physician letter and the reminder postcard. We then used chi-square tests with 1 *df* to compare each of the interventions with the control condition. These pairwise comparisons were repeated with a logistic regression model that included all the baseline characteristics. In addition, we fit five separate logistic models to test for these interactions: (1) physician letter with patient age and (2) reminder postcard with patient age, appointment wait time, travel time, or history of mammography.

Results

The groups did not differ significantly with respect to mean age (61 years) or average length of enrollment (10.4 years). As shown in Table 1, there were no significant differences among the four treatment groups on any of the baseline characteristics (Table 1).

The groups that received the reminder postcard had significantly greater rates of mammography use compared with control subjects (Table 2, $P < .001$). The odds of getting a mammogram increased at least 60% in the groups receiving a reminder postcard. The use of a letter from the woman's personal physician did not increase participation.

Adjusting for baseline covariates increased the odds ratio for both postcard groups to nearly 2 (Table 3). We did not find significant interactions between the physician letter and patient age, nor between the postcard reminder and the variables of age, appointment wait time, distance from the screening center, or having had a prior mammogram.

The covariate analysis also identified three baseline characteristics associated with a lower likelihood of obtaining a mammogram: reporting fair or poor health ($P = .02$), current cigarette smoking ($P = .0001$), and living more than 45 minutes from the screening center ($P = .0001$). Women who had had a previous mammogram were significantly more likely to participate ($P = .0001$). Because women had an average enrollment of 10 years, most of the previous mammograms occurred at the Group Health Cooperative.

Discussion

A letter from the woman's primary care physician did not increase the likelihood that she would get a mammogram within 1 year. In contrast, sending a subsequent reminder postcard nearly doubled the odds of participation.

McPhee and Detmer[29] recently demonstrated that mailed recommendations nearly doubled the odds that women would get a mammogram (62% vs 46%). Our study suggests that adding a reminder postcard 2 months after mailed recommendations would increase the rate even more.

Our results should encourage the evaluation of mailed reminders in economic or racial subgroups who were not represented in this study. Efforts to promote mammography use in Hispanic and Black populations currently emphasize encouraging physician recommendations.[30,31] However, a physician recommendation alone may not be sufficient to change behavior. Testing the effectiveness of reminders among these populations, once they receive the recommendation, would be a logical extension of our work.

The lack of effect of personal physician letters in this health maintenance organization setting may not generalize to the fee-for-service practice. In this study, the letter from the screening program medical director largely reflects the recommendation of the woman's physician. However, in fee-for-service practice, direct correspondence with women by a third party such as a radiology facility would be contrary to accepted notions of continuity. The role of continuity in achieving cancer screening goals needs closer evaluation, especially in fee-for-service practice.[32,33]

When considered in a national context, the results of this study suggest that future work to promote mammography must continue to be concentrated on women who have never obtained a mammogram. Our results demonstrate that the odds of getting a mammogram double if the woman has had a previous mammogram. Automated systems that mail reminders may be sufficient to encourage repeat mammography once a woman has had her first examination. Identifying and encouraging women who have not had the first mammogram should continue to be a priority.

Physician recommendations alone are not sufficient to ensure that women obtain a mammogram. Less than half the women who received that intervention participated, which is far less than the rates achieved in randomized trials.[20,22] More needs to be done to test methods of promoting participation. Interventions that address access barriers and patient characteristics should be compared with postcard reminders in future intervention trials.[34]

TABLE 2—Proportion of Study Group Women Who Obtained Mammograms within 1 Year

Intervention Group	Mammogram within 1 y of Recommendation, %	Odds Ratio[a]	95% Confidence Interval	P
Control[b] (n = 329)	46.8	1	...	
Primary physician invitation[c] (n = 329)	45.6	0.95	0.74, 1.36	.75

If clinic was ≥ 45 min away	0.44	0.31, 0.62	.0001
If appointment wait was ≥ 4 wk	1.04	0.74, 1.47	.68

[a]From logistic regression calculated by using all variables and 1150 subjects.
[b]Coded so that control subjects are the reference group.
[c]Coded so that the reference group is the one without the characteristic.

A variety of surveys demonstrate that older women are least likely to get screening mammography.[7,35] Our work suggests that participation rates are similar across age categories if the recommendation is given. But the recommendation alone will not be sufficient to achieve high rates of participation among women of any age group.

Automated reminder systems applied to populations show promise as a technique for putting the potential mortality reductions afforded by screening mammography within reach. Improved interventions and the use of reminders in the fee-for-service setting need future evaluation. □

The Characteristics of Northern Black Churches with Community Health Outreach Programs

Stephen B. Thomas, PhD, Sandra Crouse Quinn, PhD, Andrew Billingsley, PhD, and Cleopatra Caldwell, PhD

ABSTRACT

Objectives. The Black church has a long history of addressing unmet health and human service needs, yet few studies have examined characteristics of churches involved in health promotion.

Methods. Data obtained from a survey of 635 Black churches in the northern United States were examined. Univariate and multivariate statistical procedures identified eight characteristics associated with community health outreach programs: congregation size, denomination, church age, economic class of membership, ownership of church, number of paid clergy, presence of other paid staff, and education level of the minister.

Results. A logistic regression model identified church size and educational level of the minister as the strongest predictors of church-sponsored community health outreach. The model correctly classified 88% of churches that conduct outreach programs. Overall, the model correctly classified 76% of churches in the sample.

Conclusions. Results may be used by public health professionals and policy makers to enlist Black churches as an integral component for delivery of health promotion and disease prevention services needed to achieve the Year 2000 health objectives for all Americans. (*Am J Public Health.* 1994;84:575–579)

Introduction

Growing disparities in life expectancy and health status of Black Americans compared with Whites threaten the well-being, economic productivity, and social progress of our society as we approach the 21st century. Differences in the health status of Blacks and Whites have been documented in the United States as long as health data have been collected. These differences have persisted in spite of large increases in life expectancy and improvements in the health status of the general population. Health status is profoundly affected by poverty and racism. Poverty is the single most profound risk factor for disease.[1,2] Poverty with its concomitant lack of adequate housing, nutrition, and access to health care contributes greatly to the death toll on Black Americans. Failure to close the gap in health status between Whites and Blacks can also be directly attributed to lack of access to health care. George Lundberg, MD, editor of the *Journal of the American Medical Association,* attributes this lack of access to long-standing, institutionalized racial discrimination.[3]

One must be mindful that race of an individual is not an independent risk factor. In other words, Blacks do not have higher morbidity and mortality rates than Whites because they are Black. The landmark Black Report in Great Britain demonstrated that after decades of universal access to health services, health status inequalities between Whites and Blacks not only persisted, but were increasing.[1] In response to this evidence, William McBeath, Executive Director, American Public Health Association, stated that in America, "[W]e must assure access, not only of medical care, but also to a better standard of living—assuring nutritious food, basic education, safe water, decent housing, secure employment, and adequate income—these are the prerequisites of a healthy life-style."[1] In the absence of these prerequisites, the health status of Black Americans will continue to be cause for righteous indignation well into the 21st century.

In 1990, Dr Louis Sullivan, Secretary of Health and Human Services, presented to the nation *Healthy People 2000: National Health Promotion and Disease Prevention Objectives.*[4] These objectives include special population targets for decreasing the disparity in health status and can provide a framework for health promotion and disease prevention activities conducted through the Black church. In this article we focus on results obtained from a survey of Black churches in the northern United States and describe how the Black church can contribute to the goal of achieving health for all Americans by the year 2000.

The Black church has historically been a major focus of the spiritual,

social, and political life of Black Americans. Billingsley and Caldwell[5] state that 84% of Black adults consider themselves to be religious and almost 70% are members of a church. Lincoln and Mamiya[6] estimate Black church membership at 24 million. It is also estimated that 65 000 to 75 000 Black churches of various denominations exist in the United States.[5]

The church has a long history of addressing unmet health and human service needs of the Black community.[7–9] As long ago as the 1920s, Mays and Nicholson[10] conducted a study of 609 urban churches and 185 rural churches. The authors found that community outreach programs included various activities aimed at addressing health needs, such as (1) programs to feed the unemployed, (2) free health clinics, (3) recreational activities, and (4) child care programs.

The existence of social networks and social support through the church provides the opportunity for health promotion programming.[8] Health programs that focus on behaviors that can be reinforced by social support are a natural arena for churches. Additionally, social and emotional support offered through church programs is perceived as an essential means to prevent the isolation that results from illness.

Historically, the Black church has been used by public health and medical professionals to gain access to those Blacks who are more difficult to reach through mainstream systems. The National Negro Health Movement, 1915 to 1950, represents the best historical example of how the Public Health Service utilized the church in a national strategy to bring modern public health practices to Blacks. The health status disparities that justified the need for a National Negro Health Movement are present today and demand that systematic research be conducted to determine how the vitality within Black churches may best contribute to reaching the objectives stated in *Healthy People 2000.*

Methods

The Black Church Family Project was a multiyear, national study of family-oriented, community outreach programs sponsored by Black churches. In 1979, the Sampling Section of the Survey Research Center of the Institute for Social Research at the University of Michigan designed a procedure to select the first nationally representative sample of Blacks for use in the National Survey of Black Americans. We assumed that the distribution of Black churches would reflect the distribution of Black households. The basic sampling frame included 76 primary sampling areas stratified by region. Data presented in this article are limited to a representative sample of 635 churches in the northern region of the United States that completed a computer-assisted telephone interview conducted during 1990 and 1991. Fifty-seven percent of the 1115 churches sampled completed the survey. Included in the category of nonrespondents were churches that were unreachable after three attempts and those churches that refused to participate.

Results

It must be noted that the Black church, like the Black community, is not homogeneous. Churches in the sample were drawn from a wide range of denominational affiliations. Baptist churches accounted for approximately 44% of the sample. Forty percent of these Baptist churches belonged to the National Baptist Convention—USA, Inc. Methodist churches represented 13% of the sample; of these, over 75% belonged to the African Methodist Episcopal, the African Methodist Episcopal Zion, and the Christian Methodist Episcopal denominations. Pentecostal churches represented 25.8% of the sample. Other churches—which included the Episcopalians, Presbyterians, the Church of God in Christ, Seventh Day Adventists, and smaller denominations—constituted 17.6%. Although the vast majority of churches (91%) had no paid female clergy, it is noteworthy that women constituted 50% to 100% of congregation members in 562 (88%) of the churches in the sample.

When senior ministers were questioned about the primary role of the contemporary Black church (membership service or community service), 5% emphasized serving the membership only and 9% indicated service to the community only, whereas the vast majority (86%) indicated that the role of the church was to serve church members and the community. The data revealed that 426 churches (67%) sponsored a total of 1804 community outreach programs. It was common to find multiple programs being operated by the same church. For example, 67% of churches operate one or more community outreach activities; 54% operate two or more community outreach activities; and almost 41% operate three or more community outreach activities.

An examination of the 1804 programs revealed that 51% were adult and family support programs, 31% were oriented to children and youth, 9% focused on community development, and 9% were programs for the elderly. Programs for children and youth addressed health issues including, but not limited to, human sexuality, acquired immunodeficiency syndrome (AIDS) education, drug abuse prevention, pregnancy prevention, and mental health.

Family programs focused heavily on the provision of basic human services like food, shelter, and child care. For those churches focusing on human service needs, the majority reported that participants were primarily low income. An examination of programs targeted to adults and families demonstrated a focus on counseling for AIDS risk reduction, drug abuse prevention, services to men and women in prison, and other health issues. Programs for the elderly focused on home health care, food delivery, medical care, and other basic human services. Furthermore, other health-related services included health clinics, screening for specific health problems, and health education workshops on various topics. Additionally, domestic violence programs for women and mental health programs for both youth and adults were sponsored. In detailed descriptions of 383 selected programs, we found that 94% of the programs providing basic human needs, counseling, and education were staffed primarily by volunteers.

An examination of data on the respondent's (typically the respondent was the senior minister) perceptions of community problems provides additional evidence that health issues are central to the mission of the church. Approximately 54% of ministers sampled considered drug abuse as the most serious problem in their community. Related programs included drug abuse counseling, AIDS support and prevention programs, drug education seminars, and sponsorship of Alcoholics and Narcotics Anonymous meetings.

The Black Church Family Project data also provide evidence that the churches sampled collaborate with secular service agencies and other churches. There were 450 churches (71%) identi-

fied as having cooperative relationships with secular agencies. Table 1 identifies the types of agencies involved. Additionally, over 60% of churches collaborate with other churches in the same denomination as well as with churches of other denominations.

The existence of church programs that have collaborative relations with agencies such as welfare departments and that provide basic human services such as shelter and food indicates an ability to reach potentially underserved, poorly served, and never-served segments of the Black community. Collaborative relations with secular agencies may be strategically used to provide social support for health promotion and disease prevention initiatives designed to meet the Year 2000 health objectives.

Characteristics that influence participation in community outreach activities include church size, denomination, church age, economic class of membership, church ownership, number of paid clergy, existence of other paid staff, and education level of the minister (Table 2). Examination of data on church size demonstrates that a greater proportion of medium-size (78%) and large-size churches (88%) were involved in outreach programs.

Baptist, Pentecostal, and Methodist churches constituted 82% of the entire sample. Although a majority of these churches were actively involved in community outreach programs, some denominational differences were observed. Although there were more Baptist churches in the sample, a greater proportion of Methodist churches (77%) conducted outreach programs compared with Baptist churches (62%) and Pentecostal churches (65%).

The number of years the congregation had existed was an important factor. Approximately 78% of the churches over 75 years old reported involvement in community outreach, compared with 72% of churches between 41 and 75 years old and 62% of churches younger than 41 years old.

Economic class composition of the congregation was another important factor. Eighty percent of churches with a majority of members from the middle class sponsored community outreach programs. This figure declined to 71% among churches with congregations composed of members from the working and middle classes and dropped again to 59% among churches with congregations composed predominantly of working-class members.

Church ownership appeared to be another important factor. Overall, 70% of churches with paid mortgages engaged in community outreach programs. However, only 41% of church renters conducted outreach programs. This finding highlights the importance of the availability of church resources that may help to sustain and expand outreach programs. Additionally, ownership is related to a sense of independence and pride, both essential to the continuation of self-help and community health outreach.

The number of paid clergy was also associated with the conduct of community outreach programs. Only 49% of churches with no paid clergy were

involved in outreach. For those churches with two paid clergy, over 86% offered outreach programs.

In addition to clergy, other paid staff are human resources who also contributed toward greater involvement in community outreach. Overall, 56% of churches with no additional paid staff engaged in outreach, whereas 78% of churches with paid staff conducted outreach programs.

Finally, it is noteworthy that the minister's level of education was strongly associated with church outreach activities. For example, only 40% of those churches whose minister had less than a high school education offered outreach programs compared with 83% of those churches whose ministers had a graduate degree.

The eight variables described in Table 2 were entered simultaneously into a logistic regression model. In this multivariate model (Table 3), church size and education level of the minister remained independent predictors of church outreach activities. Based on these variables, the logistic regression model correctly classified 88% of churches that conduct community health outreach programs and 51% of churches that did not participate in outreach activities. Overall, the model correctly classified 76% of churches in the sample.

Discussion

In summary, this study identified eight church characteristics that may be used by public health professionals to identify churches that conduct community health outreach programs. When these characteristics were analyzed in a multivariant model, church size and education level of the minister proved to be the strongest predictors of church-sponsored community health outreach programs.

Although the institution of the Black church has traditionally been sustained largely by volunteers, this study suggests that the availability of paid clergy and other paid staff to provide consistent leadership to various programs is a necessary factor that will determine the extent to which the church can continue the provision of community health outreach programs. Additionally, health professionals who belong to churches could provide a critical source of expertise and could be mobilized as volunteers to guide and implement community health programs. Although women comprise the majority of church members, they remain underrepresented in the ranks of paid clergy. However, their contribution as volunteers in sustaining church programs must be acknowledged.

Some may argue that the church may be unable to reach those populations most adversely affected by pressing public health problems such as tuberculosis, human immunodeficiency virus (HIV), violence, and substance abuse. However, results of our study demonstrate that Black churches work in collaboration with secular agencies such as prisons, local police departments, welfare departments, and public housing offices. This finding suggests that churches are already involved in delivery of services to poorly served, underserved, and never-served segments of our society. Unfortunately, there has been little systematic evaluation of the quality and efficacy of these efforts, nor have they been acknowledged in the public health literature.

Many churches struggle with moral issues related to the sexual and drug behaviors at the root of health problems such as substance abuse, HIV disease, and violence. For example, substantial opposition to needle exchange and condom distribution programs has been generated by Black churches in various cities.[11] In such cases involving controversial issues that conflict with church tenets, secular agencies may provide appropriate resources. This can free the church to focus on services that are more congruent with its mission.

This study identified characteristics associated with community health outreach that may be used by public health professionals to identify those Black churches most likely to be supportive of efforts to expand health promotion and disease prevention activities. Public health professionals should collaborate

with these churches by helping them focus community health outreach programs on specific *Healthy People 2000* objectives relevant to the target population and within the capability and scope of church resources and expertise.

It is noteworthy that graduate education of the minister is strongly associated with community health outreach. The Black clergy has historically provided social, political, and religious leadership to the Black community. Therefore, joint degree programs between schools of theology and schools of public health could train a cadre of ministers who could expand their sphere of influence to provide leadership on public health issues.

Finally, closing the health status gap between Black and White Americans will require public health professionals to draw on the strength, commitment, and credibility of the Black church supported by an adequate infrastructure. As the movement for national health care reform continues to grow, it will become necessary for public health professionals and policymakers to incorporate the Black church as an integral component for delivery of health promotion and disease prevention services needed to achieve the Year 2000 health objectives for all Americans.[11,12] □

The Impact of the Safe Kids/Healthy Neighborhoods Injury Prevention Program in Harlem, 1988 through 1991

Leslie L. Davidson, MD, MSc, Maureen S. Durkin, PhD, DrPh, Louise Kuhn, MA, MPH, Patricia O'Connor, PhD, Barbara Barlow, MD, MS, and Margaret C. Heagarty, MD

ABSTRACT

Objectives. This study evaluated the effectiveness of a community coalition to prevent severe injuries to children in Central Harlem, New York, NY. It was hypothesized that injury incidence rates would decline during the intervention (1989 through 1991) relative to preintervention years (1983 through 1988); that the decline would be greatest for the targeted age group (5 through 16 years) and targeted injury causes (traffic accidents, assaults, firearms, outdoor falls); and that the decline would occur in the intervention community rather than a control community.

Methods. Surveillance of injuries that result in hospitalization and/or death among children in the two communities has been under way since 1983. Data from this surveillance were used to test whether the incidence of severe injury declined during the intervention; other temporal variations were controlled by Poisson regression.

Results. The incidence of injury among school-aged children in central Harlem declined during the intervention. The decline was specific to the targeted age group and targeted causes. A nonspecific decline also occurred in the control community.

Conclusions. The declining incidence rate in Central Harlem is consistent with a favorable program effect, but additional investigation of possible secular trend or spillover effects is needed. (*Am J Public Health.* 1994;84:580–586)

Introduction

Injury prevention has become a major public health goal in the United States[1] and community-based programs are widely recommended as a key strategy for the prevention of injuries,[2–4] but such programs are seldom evaluated rigorously. Because of variations in patterns of injury rates among communities, local surveillance systems must not only provide direction for the development of community-based programs but must also monitor and evaluate these programs.[4,5] In this report we present an evaluation of the effects on the incidence of severe injury of a community-based program, the Safe Kids/Healthy Neighborhoods Coalition, in Central Harlem, New York City.

Central Harlem health district is a disadvantaged community in New York City with a predominantly non-Hispanic Black population. It is contiguous to Washington Heights health district, a largely Hispanic community, which is slightly less disadvantaged. In 1990, 39.5% of Central Harlem residents lived below the poverty level, compared with 30.7% of Washington Heights residents and 19.3% of city residents as a whole (Table 1). Together the two communities, which constitute Northern Manhattan, contain 5.9% of New York City residents younger than 17 years.

The Northern Manhattan Injury Surveillance System (NMISS) was established at the two major hospitals serving these communities covering the years from 1983 onward. This system monitors the incidence of severe pediatric injuries (defined as those resulting in hospitalization or death). Preintervention surveillance data for the years 1983 through 1987 revealed three patterns: (1) the incidence of severe injuries was twice as high in Central Harlem as in Washington Heights; (2) the incidence was increasing among school-aged children (those aged 5 through 16 years) while declining among younger children (newborn through 4 years); and (3) the leading causes of severe injuries were falls and motor vehicle collisions. Assault was the cause of 9% of injury hospitalizations and 36% of injury deaths. Gunshot wounds were a major cause of fatal injuries (14%) to children in Harlem[6] and in New York City as a whole.[7]

Safe Kids/Healthy Neighborhoods Coalition

Parents and educators in Central Harlem requested a program in playground safety from health professionals. Surveys of the playgrounds revealed that they were sites for drug dealing and were in poor repair. Children in these play areas had very little adult supervision. The absence of safe play areas and

At the time of the study, Leslie L. Davidson was with the Gertrude H. Sergievsky Center and Division of Epidemiology, Columbia University, and the Department of Pediatrics, Harlem Hospital Center, New York, NY. Maureen S. Durkin and Louise Kuhn are with the Gertrude H. Sergievsky Center and Division of Epidemiology, Columbia University. Patricia O'Connor is with the Department of Psychology, Russell Sage College, Troy, NY. Editor's Note. See related editorial by Pless (p 537) in this issue.

supervised play activities for children was hypothesized to contribute to the high rates of outdoor injuries and assaults found among children in Harlem.

On the basis of these observations, at the end of 1988 the Harlem Hospital Injury Prevention Program, in collaboration with a variety of community groups and city agencies, initiated the Safe Kids/Healthy Neighborhoods Coalition, the initial goal of which was to reduce outdoor injuries. The Coalition soon grew to include assaults to school-aged children and developed alliances with city and community agencies and the private sector. Specifically, the Coalition worked to (1) renovate Central Harlem playgrounds; (2) involve children and adolescents in safe, supervised activities that would teach them useful skills (dance, art, sports, horticulture, carpentry); (3) provide injury and violence prevention education; and (4) provide safety equipment (bicycle helmets) at reasonable cost.

The development of the Safe Kids/Healthy Neighborhoods injury prevention program is described more fully elsewhere.[9] Over the first 3 years (1989 through 1991), 26 organizations (departments of city agencies, voluntary organizations, citizen groups) participated in the intervention. (Participation is defined as attending two or more planning meetings in any 1 year.) Injury prevention programs and activities were developed steadily over the period and involved large numbers of community children. The Department of Parks undertook repair of all playgrounds, including major capital improvements to five parks and playgrounds, and involved over 100 children in mural painting (three murals were completed). The Department of Transportation initiated an intensive pedestrian safety program that has reached all third-grade pupils in Harlem since 1990; the department has conducted other traffic safety education as well. The Harlem Hospital Injury Prevention Program initiated a dance program, an art studio, a Little League program, a winter baseball clinic, and a soccer league that have involved over 1000 children. Through bicycle safety programs, more than 500 bicycle helmets have been made available to the community.

Source. Data are from the 1980 and 1990 US censuses.[11,12]

Methods

Injury Hospitalizations and Deaths

Severe injury is defined as an injury resulting in hospitalization and/or death and refers to the *International Classification of Diseases* (ninth revision) external cause of injury codes (E-codes) between 800 and 999, which incorporate all trauma, poisonings, and burns that result from intentional, unintentional, and undetermined external causes.[10] Complications of hospitalization (E870–879) and therapeutic overdose (E930–949) are excluded from the definition. The study was restricted to residents of Northern Manhattan younger than age 17 (the criterion for admission to pediatric wards at one of the study hospitals) who were injured during the years 1983 through 1991.

Injury data for hospitalized cases were abstracted from the medical records of the two primary hospitals serving the area. Over the 9 years of the study, the data were abstracted by two physicians and a graduate student trained by an injury epidemiologist and pediatric surgeon. E-codes abstracted from the medical records were compared with E-codes on the discharge summary. Discrepancies were resolved in consultation with the injury epidemiologist. Pilot studies of data abstraction procedures showed high agreement between reviewers and data were routinely checked for accuracy.

Data on fatal injuries were obtained from New York City death certificate files. Reported deaths that occurred following admission to one of the two hospitals were verified in the data from the hospital records. The injury deaths among children who lived in the study area but who had not been admitted to one of the study hospitals were added. NMISS consists of the injury hospitalization and death data collected in this manner.

Adjustment for Incomplete Study Hospital Coverage

A comparison between NMISS data and the New York State Uniform Hospital Discharge Data (UHDD) revealed that 76% of all child residents of Northern Manhattan hospitalized for injury were admitted to one of the two study hospitals during the years 1983 through 1988. Since UHDD did not include the cause of injury until 1990, UHDD could not be used for the analysis directly. Instead, UHDD were used to adjust the incidence rates to compensate for the degree to which the data from the two hospitals underestimate the true incidence. This was done in the following manner. Within UHDD, the proportion of all injury-related hospitalizations in the study population admitted to one of the two study hospitals was calculated separately for each health district and for each year. Injury incidence in NMISS was adjusted by this proportion in each area and each year

TABLE 2—Numbers of Injuries and Mean Annual Adjusted Incidence Rates for All Causes of Severe Injury, by Age Group and Area

	Central Harlem		Washington Heights	
	Newborn–4 y	5–16 y	Newborn–4 y	5–16 y
No. injuries (1983–1991)				
Nonfatal	680	1217	975	1516
Fatal	29	37	34	14
Mean annual adjusted incidence rates[a]				
All severe injuries (1983–1991)	1251	968	611	468
Injury mortality (1983–1991)	37.9	21.2	17.6	11.4
All severe injuries, preintervention (1983–1988)	1382	1035	655	509
All severe injuries, intervention period (1989–1991)	989	833	523	387

[a]Adjusted rates (per 100 000 population) were calculated with numerators from the Northern Manhattan Injury Surveillance System, adjusted by the proportion estimated from Uniform Hospital Discharge Data to be hospitalized in other hospitals, and weighted averages of the population from the 1980 and 1990 US censuses.

separately. In 1989, 1990, and 1991 an average proportion for the preceding 6 years was substituted because UHDD for those years were found to be incomplete. The adjustment assumes that the cases treated in hospitals other than the two study hospitals were distributed by external cause in the same way as those in the database from the two hospitals. A comparison of the age, sex, racial, and broad diagnostic distributions of cases in the two data sets for 1983 through 1988, when UHDD were complete, show no major differences and suggest that this assumption is valid.[6] Distribution by E-code could not be compared because this information was not included in UHDD until the end of the study period.

Population Denominators

The US census (1980 and 1990) provided the population denominators for the two areas and two age groups (newborn through 4 years and 5 through 16 years).[11,12] A weighted average for each intercensus year was calculated for each area and age group. For example, the population estimate for the Central Harlem 0- through 4-year-old age group in 1984 was estimated as 60% of the 1980 count plus 40% of the 1990 count for the same area and age group.

Table 1 summarizes the demographic characteristics of the two communities from the 1980 and 1990 censuses. Substantial increases in the population occurred in Central Harlem in the younger age group and in Washington Heights in both age groups. Increases in birth rates in the two health districts during the past decade corroborate these census figures. Between 1980 and 1990, no striking changes occurred in the composition of the two health districts with respect to ethnic and economic indicators.

Statistical Analysis

The study design involves comparisons between the incidence rates of severe injuries during the intervention period (1989 through 1991) and those during the preintervention period (1983 through 1988). Three sets of comparisons are presented: (1) 5- through 16-year-old children vs newborn through 4-year-old children in Central Harlem (i.e., the rates in the targeted age group are compared with those in the nontargeted age group within the area in which the program was implemented); (2) 5- through 16-year-old children in Central Harlem vs children of the same age in Washington Heights (i.e., the rates in the area in which the program was implemented are compared with those in the neighboring community in which no specific injury prevention had occurred within the targeted age group); and (3) targeted vs nontargeted injuries among 5- through 16-year-old children in Central Harlem and in Washington Heights. Targeted injuries included all injuries related to vehicles, outdoor falls, assaults, and guns, regardless of intent. Nontargeted injuries included all others (poisonings, ingestions, burns, etc.). The three comparisons are used to strengthen inferences about the effect of the intervention by replicating the findings using different approaches to the data.

Incidence rates (adjusted as described above) for all injuries and for targeted and nontargeted injuries separately were calculated in 36 quarterly (3-month) intervals over the 9-year period for each age category (5 through 16 years and newborn through 4 years) and each area (Central Harlem and Washington Heights). Date of death or admission was used to indicate the quarter in which the injury occurred. Each case was assigned to a census tract, and therefore to either the Central Harlem or the Washington Heights health district, on the basis of the child's residential address.

The method of Poisson regression was used. The dependent variable was the injury rate in each quarter, which was modeled as a function of year (coded as a continuous variable), to account for net secular trends; season (coded as a four-way categorical variable), to account for marked increases in injury in the summer quarter; and intervention period (coded as a categorical variable corresponding to the time period before and after the development of the intervention). Poisson regression models can be understood as a subclass of generalized linear models in which the distribution of the error is assumed to be Poisson, the systematic effects are multiplicative, and the link function is log linear.[13–18] In each age and area category separately, Poisson regression models for rates of all injury and targeted and nontargeted injury types were fitted by means of maximum likelihood estimation and the statistical package GLIM.[19]

Poisson regression models have the useful feature of allowing the regression parameters to be interpreted as the log of the relative risk, adjusted for the other predictors in the model. In this case, the log of the regression parameter for the intervention period indicated the relative risk of injury following the intervention to that before the intervention, with annual and seasonal variations in injury incidence controlled. If, for example, incidence rates were decreasing prior to the intervention, then only if the decrease in the injury rate following the intervention was greater than this antecedent secular trend would the relative risk from the regression model indicate some protective effect of the intervention.

Results

Descriptive Epidemiology

Rates of severe injury hospitalization and mortality in the study population over the 9-year period of surveillance are displayed in Table 2 by age group and area. The injury rates for all severe injuries were approximately twice as high in Central Harlem as in Washington Heights for both age groups and declined for both areas and age groups over time.

Time Trends and Poisson Regression Analysis

Central Harlem: Comparison of incidence rates for the targeted and nontargeted age groups. The adjusted annual incidence rates of injuries in Central Harlem are plotted in Figure 1 for the two age groups. The rates can be seen to vary widely from year to year and appear to be decreasing over time in both age groups.

Poisson regression results show a significant decrease during the intervention period in the targeted age group (relative risk [RR] = 0.74, 95% confidence interval [CI] = 0.62, 0.89; Table 3). The intervention period is thus associated with a 26% reduction in the overall injury rate during the 3 years after the initiation of the prevention program compared with the 6 years before. In the younger, nontargeted age group, by contrast, no significant reduction in incidence occurred (RR = 1.06, 95% CI = 0.83, 1.35; Table 3). These relative risks are adjusted for annual and seasonal trends independent of the intervention. The model for children aged 5 through 16 years incorporates a marked seasonal effect but no significant annual trend. For younger children, seasonal trends are less consistent but the coefficient for annual trend is significant, reflecting a decrease in incidence with each sequential year.

School-aged children: Comparison of incidence rates for the targeted and nontargeted areas. The adjusted annual rates of injury from all causes in Central Harlem and Washington Heights for the age category 5 through 16 years are displayed in Figure 2. There appears to be a reduction in both areas in the last 3 years in this age category. The rates are substantially higher in Central Harlem than in Washington Heights in all years. Both areas show variability from year to year. The regression models show a

[a]Adjusted rates (per 100 000 population) were calculated with numerators from the Northern Manhattan Injury Surveillance System, adjusted by the proportion estimated from Uniform Hospital Discharge Data to be hospitalized in other hospitals, and weighted averages of the population from the 1980 and 1990 US censuses.

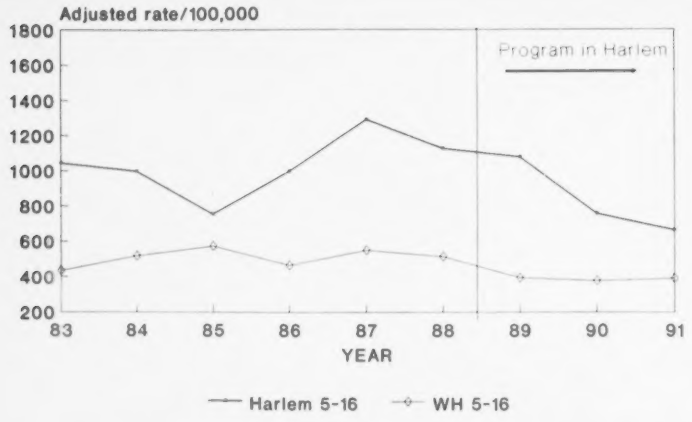

FIGURE 2—Adjusted annual rates per 100 000 population for all injuries in Central Harlem and Washington Heights (WH) to children aged 5 through 16 years.

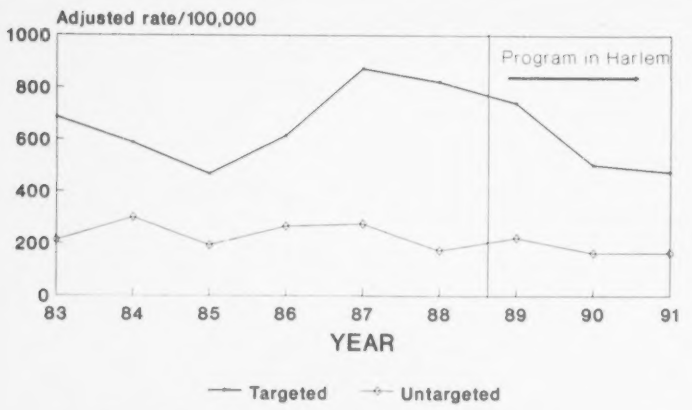


Note. Targeted injuries are injuries related to motor vehicles, outdoor falls, guns, and assaults.

FIGURE 3—Adjusted annual rates per 100 000 population for targeted and nontargeted injuries in Central Harlem to children aged 5 through 16 years.

significant reduction for 5- through 16-year-olds in Washington Heights (RR = 0.70, 95% CI = 0.59, 0.83; Table 3). This reduction is slightly greater than the reduction observed in Central Harlem in the same age group. In the younger age group in Washington Heights, there is no significant reduction (RR = 0.96, 95% CI = 0.77, 1.19).

Central Harlem and Washington Heights: Comparison of incidence trends for targeted and nontargeted injuries. The adjusted annual incidence rates of targeted and nontargeted injuries among children aged 5 through 16 years in Central Harlem are displayed in Figure 3. The regression models show that in Central Harlem the decline during the intervention period is differential, affecting targeted injuries (RR = 0.56, 95% CI = 0.45, 0.71) but not other injuries (RR = 1.03, 95% CI = 0.78, 1.35; Table 4). Within the targeted injury category in Central Harlem, motor vehicle and assault injuries decreased significantly while outdoor falls did not. Figure 4 displays the adjusted annual incidence rates of targeted and nontargeted injuries among children aged 5 through 16 years in Washington Heights. In Washington Heights, the decline in incidence during the intervention period occurred only for motor vehicle injuries (Table 4).

Discussion

Few published evaluations of community-based injury prevention programs have used changes in injury rates as outcome measures. The Massachusetts statewide injury prevention program demonstrated a reduction in incidence in one of its targeted injury subtypes, motor vehicle occupant injuries.[20] In Sweden, a 4-year grassroots community-based injury prevention program showed postintervention decreases in home injuries (27%), occupational injuries (28%), and motor vehicle injuries (28%).[21] Both studies used a comparison between pre- and intraintervention injury rates in study and control communities. A study in the US Indian Health Service used regression analysis to demonstrate a program effect on changes in hospitalization rates for injury.[22]

This evaluation of the Harlem Safe Kids/Healthy Neighborhoods Coalition provides findings that are consistent with the hypothesized favorable effect of the program in reducing the incidence of severe injuries. It also produced findings that detract from the hypothesized effect. In favor of the hypothesis is the estimated 44% reduction in injury risk for targeted injuries in school-aged children in Central Harlem during the intervention period relative to the preintervention period. Moreover, the decrease within Central Harlem was specific to the age group (5 through 16 years) and largely specific to the injury types targeted by the prevention program. A finding not consistent with the study hypothesis is the significant decline in incidence also observed in the control area, Washington Heights (an estimated 30% reduction), for all severe injuries to school-aged children. The decline in Washington Heights occurred for both all targeted and all nontargeted causes, and, within the targeted category, it was restricted to motor vehicle injuries. Our conclusion from these mixed findings is that because the decline in incidence was specific to targeted injuries only in the intervention area, there is cause to be optimistic

about the effectiveness of the prevention program. At the same time, the significant reduction in motor vehicle injuries (one of the targeted causes) in both the intervention and control areas weakens the evidence in favor of the program's effectiveness in preventing this leading cause of injury.

The study also demonstrates the need for caution in using routinely collected hospitalization data for evaluation: had we used only the New York State UHDD for the follow-up period and not collected local surveillance data from hospital records, we would not have known that the UHDD were incomplete. This would have biased our results in favor of the hypothesis, for we would have found a spuriously low rate in the Harlem area compared with the Washington Heights area, for which the UHDD were more complete. The incomplete UHDD means that changes in referral patterns in the period since the intervention cannot be assessed. The adjustment makes the assumption that there were no such changes.

The observed decline in motor vehicle injuries, which for Northern Manhattan residents are predominantly pedestrian injuries, could be due to (1) a general decline in motor vehicle injuries, independent of any effects of the Safe Kids/Healthy Neighborhood Injury Prevention Program, or (2) a program effect that "spilled over" to the control area. In support of the first of these alternatives is a general national decline in motor vehicle death rates since 1989.[23] In support of the second alternative, preliminary data on the residence of program participants demonstrate that an increasingly large proportion (29%) of all participants in the program between 1989 and 1991 lived in Washington Heights. Further research is needed to investigate these hypotheses.

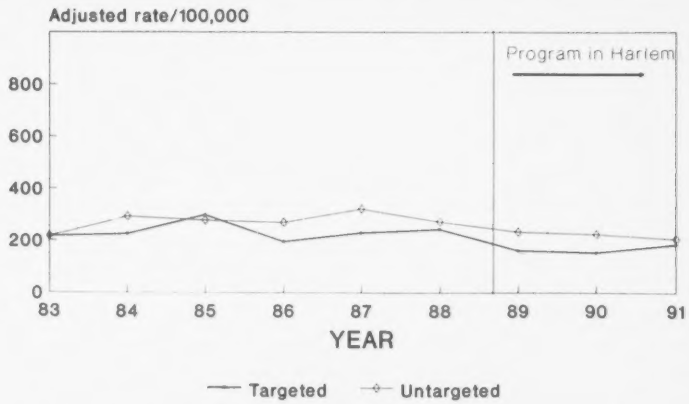
Another finding that is difficult to explain is the absence of a significant change in the incidence of outdoor fall injuries, a major cause of injury targeted by the program. One possible explanation for this finding is that the program activities are not effective in preventing outdoor fall injuries. The program contained no specific elements that addressed the problem of falls; rather, it focused on general improvements in environmental hazards (e.g., repair of dangerous fences and the provision of safer equipment) and increased supervision. The provision of many new supervised sports activities in the area may have actually resulted in an increased exposure to the risk of outdoor falls. Another possibility is that our ability to distinguish outdoor from indoor fall injuries was not adequate and that our measure of outdoor fall injuries was, therefore, not sufficiently valid to detect a change due to the intervention. The E-codes used to classify causes of injury do not always distinguish outdoor from indoor falls and data on location of injury event are incomplete. Cases for which the information was incomplete for classifying the location of falls were included in the untargeted group.

Despite these limitations, this study demonstrates the usefulness of injury surveillance both for guiding the development of a community-based and locally relevant injury prevention program and for evaluating the impact of such a program on injury incidence. In 1987, NMISS showed a dramatic increase in assault injuries and high rates of motor vehicle–pedestrian and fall injuries among school-age children in Central Harlem. It was these data that gave impetus and direction to the Safe Kids/Healthy Neighborhoods Injury Prevention Program in Central Harlem, initiated in 1988 and still active in 1993. The same surveillance system is providing the necessary data to evaluate the effects of the prevention program activities on the

TABLE 4—Effect of Intervention, with Year and Season Controlled, on Targeted and Nontargeted Adjusted Quarterly Injury Rates among Central Harlem and Washington Heights Children Aged 5 through 16 Years

	Central Harlem			Washington Heights		
	No.	RR	95% CI	No.	RR	95% CI
All targeted injuries[a]	664	0.56	0.45, 0.71	683	0.68	0.52, 0.87
Assault	199	0.52	0.34, 0.79	136	1.13	0.63, 2.03
Motor vehicle	302	0.45	0.32, 0.64	375	0.47	0.34, 0.66
Outdoor falls	121	1.35	0.75, 2.42	138	0.89	0.49, 1.54
Guns	100	0.56	0.31, 1.02	67	1.58	0.68, 3.66
All nontargeted injuries[b]	580	1.03	0.78, 1.35	833	0.71	0.57, 0.90

Note. RR = relative risk; CI = confidence interval.
[a]Targeted injuries include all assault injuries and all injuries related to motor vehicles, outdoor falls, and guns, regardless of intent.
[b]Nontargeted injuries include all unintentional nontrauma injuries and unintentional trauma injuries other than injuries related to motor vehicles, outdoor falls, and guns.



Note. Targeted injuries are injuries related to motor vehicles, outdoor falls, guns, and assaults.

FIGURE 4—Adjusted annual rates per 100 000 population for targeted and nontargeted injuries in Washington Heights to children aged 5 through 16 years.

incidence of severe injuries to children in Harlem. Such an evaluation is critically important for future planning of the program and, to the extent that the program is found to be successful, for facilitating sustained interest and support.

A major strength of this study is the use of Poisson regression to analyze injury rates over time, including periods before and during the intervention, adjusting for trends in the incidence rates that existed prior to the start of the prevention program. A simpler approach would have been to compare the mean annual incidence rates during the intervention period with those during the preintervention period. For example, for children younger than 5 years in Central Harlem the mean annual incidence rate was 28.4% lower during the intervention period than before (Table 2). The Poisson regression analysis shows a 6% increase (not statistically significant) in incidence for this age group during the intervention time period, after controlling for the annual decline in rates that occurred over the whole 9-year period. The regression approach provides a better way to detect changes likely to be due to the intervention rather than those associated with temporal variations in incidence that were present prior to the intervention. The Poisson regression approach could not be used to evaluate the impact of the program on injury fatalities because there were too few cases to produce stable quarterly mortality rates. It may be possible to use the approach in the future, using a larger control area and adding more years of data.

Another strength of this study is the use of multiple comparisons to assess the extent to which an observed reduction in injury incidence is specific to the age group, the area, and the types of causes targeted by the prevention program. The fact that these multiple comparisons gave mixed results indicates that more research is needed before a conclusion can be made about the effectiveness of the Safe Kids/Healthy Neighborhoods Coalition and injury prevention program. A simpler strategy might have provided results easier to interpret. For example, a strategy using no comparisons between age groups, areas, or causal categories would give results fully consistent with the hypothesized effectiveness of the program; a strategy using only the area comparison would support the conclusion of no measurable effect. The results of multiple comparisons have alerted us to the complexity of the temporal trends in pediatric injury incidence rates in Northern Manhattan and may have prevented us from drawing incorrect conclusions.

This study is limited to a relatively brief period of observation (3 years) following the start of the prevention program. Additional years of follow-up are needed to assess whether the decline persists and whether interventions only recently implemented have additional effect. Individual-level studies of associations between program involvement and exposure to program activities, on one hand, and injury incidence, on the other, will help to clarify the effect of the Safe Kids/Healthy Neighborhood Injury Prevention Program and its specific components on the risk of severe childhood injury in Central Harlem. These initial results are encouraging and suggest that the program is having a beneficial impact on the risk of severe injury to children in Harlem. □

Low-Income Neighborhoods and the Risk of Severe Pediatric Injury: A Small-Area Analysis in Northern Manhattan

Maureen S. Durkin, PhD, DrPH, Leslie L. Davidson, MD, MSc, Louise Kuhn, MA, MPH, Patricia O'Connor, PhD, and Barbara Barlow, MD, MS

ABSTRACT

Objectives. The purpose of this study was to investigate the relationship between socioeconomic disadvantage and the incidence of severe childhood injury.

Methods. Small-area analysis was used to examine socioeconomic risk factors for pediatric injury resulting in hospitalization or death in Northern Manhattan, New York, NY, during a 9-year period (1983 through 1991).

Results. The average annual incidence of all causes of severe pediatric injury was 72.5 per 10 000 children; the case-fatality rate was 2.6%. Census tract proportions of low-income households, single-parent families, non–high school graduates, and unemployment were significant predictors of risk for both unintentional and intentional injury. Among the socioeconomic factors considered, low income was the single most important predictor of all injuries; other socioeconomic variables were not independent contributors once income was included in the model. Compared with children living in areas with few low-income households, children in areas with predominantly low-income households were more than twice as likely to receive injuries from all causes and four and one half times as likely to receive assault injuries. The effect of neighborhood income disparities on injury risk persisted after race was controlled.

Conclusions. These results illuminate the impact of socioeconomic disparities on child health and point to the need for injury prevention efforts targeting low-income neighborhoods. (*Am J Public Health.* 1994;84:587–592)

Introduction

Childhood injuries are now recognized as a leading public health problem in the United States and other developed countries.[1–4] Studies of the incidence and risk factors of severe injuries, including nonfatal injuries, are needed to provide direction in planning and implementation of appropriate prevention programs.[5,6] Low socioeconomic status is one risk factor that is relatively well documented for injury fatality, particularly for house fires and homicide,[1,7–11] but it has rarely been investigated for the far more frequent outcome of severe nonfatal injury.[12] In general, the epidemiology of nonfatal injuries differs from and cannot be extrapolated from that of fatal injuries.[13] Another limitation of current knowledge is the absence of information on specific components of low socioeconomic status that affect a child's risk of injury.

We used methods of small-area analysis[14–17] to investigate associations at an ecological (census tract) level between multiple indicators of socioeconomic status and the incidence of severe pediatric injury in an inner-city environment in New York City. One aim of the study was to describe the variability between census tracts in socioeconomic indicators and in mean annual incidence rates during the 9-year study period. Another was to investigate the extent to which geographic variations in injury incidence are explained by variations in socioeconomic indicators. The results are presented for overall severe pediatric injury incidence rates and for broad subcategories of causes.

Methods

The study population consisted of residents of two Northern Manhattan health center districts, Central Harlem and Washington Heights, with a combined population in 1990 of 94 762 children younger than 17 years (Table 1).[18] According to major socioeconomic indicators, Northern Manhattan is disadvantaged relative to the rest of New York City, and the Central Harlem health district is disadvantaged relative to Washington Heights. For example, according to the 1990 census, 34% of the households in Northern Manhattan (40% in Central Harlem and 31% in Washington Heights) lived below the poverty level, compared with 19% in New York City as a whole.[18]

Data Sources

The Northern Manhattan Injury Surveillance System collected data on all injuries to residents of Northern Manhattan younger than age 17 that resulted in hospitalization or death during the years 1983 through 1991.[19] Data were abstracted from medical charts of the two

At the time of the study, Maureen S. Durkin, Leslie L. Davidson, and Louise Kuhn were with the Gertrude H. Sergievsky Center and the Division of Epidemiology, Columbia University, New York, NY. Patricia O'Connor is with the Department of Psychology, Russell Sage College, Troy, NY. Barbara Barlow is with the Department of Pediatric Surgery, Harlem Hospital Center, New York, NY.

Note. Northern Manhattan comprises two health center districts, Central Harlem and Washington Heights.

study hospitals (Harlem Hospital Center and Columbia-Presbyterian Medical Center, the two major hospitals serving the area) and New York City death certificates. Data on residents of other areas hospitalized in these two hospitals were excluded. Injury cases include all those with *International Classification of Diseases* (9th revision) E-codes 800 to 999, which incorporate all trauma, poisonings, and burns resulting from unintentional, intentional, and undetermined external causes. Detailed data are included in the surveillance system for all deaths (n = 162, including 33 deaths following admission to one of the two study hospitals) and for the 4592 survivors who were hospitalized in the two study hospitals during the 9-year period. Less than 2% of the hospitalizations involved readmission of the same child for injury. According to a computerized hospital discharge database maintained by the New York State Department of Health, 76% of all Northern Manhattan children with nonfatal injuries were hospitalized in one of the two study hospitals (72% of those in Central Harlem and 85% of those in Washington Heights). The incidence rates given in Table 2 of this paper were first calculated on the basis of the detailed data on patients treated in the study hospitals, then inflated by 24% to represent the proportion of residents treated in other hospitals.[19] To validate this approach, we compared patients from the study area treated in other hospitals with those treated in the study hospitals and found no major differences in age, sex, ethnicity, or frequency of diagnoses. It was not possible to compare external cause (E-code) distributions because this information was not included in computerized New York State hospital discharge data prior to 1990. The deaths (assumed to be complete) were then added. The denominators (population younger than 17 years) of the incidence rates were weighted averages obtained from US census data for 1980 and 1990.[18,21]

Socioeconomic Variables

The following socioeconomic indicators for each census tract in the study area were derived from the 1990 census: (1) low income (proportion of households with annual incomes of less than $10 000); (2) poverty (proportion of households below the poverty level); (3) single parents (proportion of family households with only one parent present); (4) non–high school graduates (proportion of the population older than 17 years who did not graduate from high school); (5) crowding (proportion of occupied housing units with two or more persons per room); (6) mothers not employed (proportion of women with children younger than 6 years old who are not employed); and (7) unemployed men (proportion of men who are unemployed). The poverty variable is derived from the variables low income and household size; we found its relation to injury risk to be similar to, if somewhat weaker than, that of low income. For brevity's sake, the results for poverty are not reported here. The frequency in the study population of each socioeconomic variable examined, as well as age and ethnic variables, is given in Table 1. After reviewing socioeconomic indicators for Northern Manhattan from the 1980 and 1990 censuses and finding no major changes over the decade, we used only the indicators from the 1990 census in this paper.

Statistical Analysis

For the small-area analyses, the unit of analysis is the census tract. Injury data from the two study hospitals for residents of 75 of Northern Manhattan's 84 tracts were used. Three tracts with fewer than 100 children and six on the boundaries of the area with high proportions of injury admissions to other hospitals were excluded from the small-area analyses to avoid instability of rates due to small denominators. Coefficients of variation[22–24] were computed for each variable by dividing the standard deviation by the mean and chi-square tests of homogeneity were done to assess whether variation between census tracts in both independent and dependent variables was larger than would be expected by chance.[24]

Consistency of the injury rates within each tract over the 9-year period was assessed with Cronbach's alpha coefficient.[25,26] Regression analyses were done only for the overall and cause-specific injury rates considered consistent or reliable (alpha coefficients greater than .40). A simple linear regression of each social indicator with a given type of injury rate and a multiple linear regression of combinations of social indicators with a given injury rate were performed.[27] Injury incidence (all causes and major subtypes) was the dependent variable and indicators of socioeconomic status were the independent variables. In the multiple regression analyses, independent variables with P values of less than .10 were entered. The R^2 is the percentage of variance in injury incidence explained by a given socioeconomic variable after any other variables in the model are controlled.

To further assess low-income neighborhood as a risk factor, we computed the ratio of the incidence rate in census tracts with moderate and large numbers of low-income households to that in a reference area composed of tracts with few low-income households. Confidence intervals around the rate ratios were computed by the Taylor series approximation.[28]

Results

Average annual incidence rates for all injuries and those due to the most frequent external causes, by age, sex, and ethnicity, are displayed in Table 2. Measures of variation between census tracts in injury rates as well as socioeconomic indicators show large and significant variations across the area (Table 3). The bivariate regression results for all injuries show large and significant positive associations with the variables low income and single parents; smaller but still significant positive associations with non–high school graduates, mothers not employed, and unemployed men; and no significant association with crowding (Table 4). The same directions of associations are seen for each category of injury cause, although the strengths and significance levels of the associations vary for different categories (Table 4).

TABLE 3—Range and Variability of Census Tract Mean Injury Incidence and Socioeconomic Indicators, and Year-to-Year Consistency[a] of the Rank Order of Tract-Level Injury Incidence Rates

	Range of Means across Census Tracts	SD	Coefficient of Variation	Cronbach's α
Socioeconomic indicators[b]				
Low income	8.1–77.3	12.47	0.35	
Single parents	4.8–59.1	12.42	0.34	
Non–high school graduates	2.4–75.6	14.35	0.25	
Crowding	0.0–8.4	1.75	0.71	
Mothers not employed	0.0–100.0	17.14	0.32	
Unemployed men	0.0–55.1	9.67	0.57	
Mean injury incidence[c]				
All injuries	3.9–160.2	36.6	0.60	.88
Unintentional injuries	3.9–127.0	28.1	0.57	.83
Assault injuries	0.0–32.8	6.6	1.03	.73
Self-inflicted injuries	0.0–6.6	1.9	1.27	.17
Injuries of undetermined cause	0.0–13.3	3.3	0.84	.30
Motor vehicle injuries	0.0–36.8	7.6	0.73	.46
Pedestrian injuries	0.0–32.9	6.0	0.86	.58
Occupant injuries	0.0–4.6	1.0	1.36	.14
Fall injuries	0.0–39.1	9.3	0.62	.66
Gunshot injuries	0.0–13.4	3.3	1.23	.46
Burn injuries	0.0–276.4	62.5	0.77	.52

[a]As indicated by Cronbach's alpha.
[b]See text for definitions.
[c]Mean annual injury incidence per 10 000 population in each of the 75 included census tracts, 1983 through 1991.

The apparent protective effect of crowding, which is significant for assaults and burns and nearly significant for gunshot injuries, is unexpected and is probably due to confounding by ethnicity. The percentage of Hispanic residents in a census tract is positively correlated with crowding (Pearson correlation coefficient = .76), and Hispanic children have lower injury rates than non-Hispanic Black children. When racial and ethnic composition of neighborhoods is controlled, crowding is no longer associated with assault, burn, or gunshot injury risk.

In the multiple regression analyses, low income (or poverty) was the strongest predictor of all injuries and of each causal category examined. Changes in the order in which the variables were entered did not affect this result. Once income is in the model, crowding continues to have a small negative effect for assault, burn, and gunshot injuries, and the effects of the remaining socioeconomic variables are insignificant.

The rate ratio estimates show a strong positive association between residence in a low-income neighborhood and risk of severe pediatric injury (overall and for each causal category) (Table 5). Compared with children in neighborhoods with few low-income households, children living in largely low-income neighborhoods have more than twice the risk of severe injury from all causes and four and one half times the risk of severe assault injury. For most injury categories considered, a dose–response association is present (Table 5).

Race, ethnicity, and socioeconomic status are highly confounded in Northern Manhattan census tracts, making it difficult to demonstrate an effect of poverty independent of racial composi-

[a]See text for definitions.
[b]Mean annual incidence per 10 000 population in each census tract, 1983 through 1991.
[c]The beta coefficient for low income can be interpreted as the change in injury incidence per 100 000 population for every 1% change in the percentage of low-income households in a census tract. The beta for single parents is the change in injury incidence per 100 000 population for every 1% change in the percentage of family households with only one parent present. The beta coefficients for the remaining independent variables can be interpreted similarly.

tion. In only 3 of 31 predominantly African-American tracts were fewer than one third of the households considered low-income. In an attempt to control for race, we computed incidence rates for non-Hispanic Black children only and found low-income neighborhood to be a significant predictor of injury risk within this group ($R^2 = .14$, $P < .001$). The marginally lower effect in this race-specific regression analysis compared with that of the total population is likely to be due to smaller variation in the proportions of low-income families in African-American neighborhoods. In a relative risk analysis of incidence of all injury types for Black children, the relative risk for low-income neighborhood is 1.9 (95% confidence interval = 1.5, 2.7), not significantly different from the effect among all children. We also tried controlling for race in a multiple regression analysis; after we entered census tract proportion of non-White residents ($R^2 = .49$, $P < .0001$, for all injuries), low income did not explain significant additional variation in injury risk (incremental R^2 for low income = .02, $P = .09$, for all injuries). Perhaps neighborhood racial composition is more accurately measured by the census and provides a better and more comprehensive marker of socioeconomic disadvantage than household income and other intended socioeconomic indicators. Thus, the confounding of poverty with race may be only partly extricable in the census measures; once race is held constant, our ability to show an effect of income is limited.

Discussion

These results show that children living in low-income neighborhoods are at increased risk of severe injury from both unintentional and intentional causes. This general finding is consistent with previous studies of fatal childhood injuries[7,9–11] but has not to our knowledge been demonstrated for the much more frequent occurrence of injury hospitalization. One study, a case–control study carried out in Belfast and published in 1959,[12] showed significant individual-level associations between several indicators of poverty and pediatric morbidity due to motor vehicle collisions.

Another case–control study of nonfatal child bicycle and pedestrian injuries found a twofold excess risk for low vs high maternal education but no signifi-

cant association with residence in an economically disadvantaged neighborhood.[29] Two other studies of nonfatal child pedestrian injuries found that more cases occurred in low-income areas than in more advantaged and less densely populated areas, but these studies did not compute population-based incidence rates to control for differences between areas in population size.[30,31] The present study, based on incidence rates and confined to an inner-city area, shows significant ecological associations between socioeconomic disadvantage and incidence of all major categories of severe pediatric injury.

The two analytic approaches, linear regression and rate ratio estimation, produced similar results except that the regression results imply that low-income neighborhood may be a slightly more important risk factor for unintentional injuries ($R^2 = .33$) than for assault injuries ($R^2 = .28$), while the rate ratio results suggest that low-income neighborhood is a much more important risk factor for assault injuries (rate ratio = 4.5) than for unintentional injuries (rate ratio = 2.0). Perhaps this is because the association between low-income neighborhood and injury risk is not linear for all causes, as assumed by the regression approach. For unintentional causes the association fits a linear model, whereas for assault injuries there appears to be a threshold effect. Limitations in the use of linear regression to estimate measures of effect, due to model mispecification and violations of assumptions regarding the distributions of the variables, have been noted.[32]

Because small-area analysis reveals ecological rather than individual-level associations, it is advantageous for identifying risk factors that operate on an ecological level.[33–35] For example, if poor neighborhoods have fewer safe play areas, more children are likely to play in the streets, abandoned buildings, and other hazardous areas. Poor neighborhoods may present other hazards, such as broken playground equipment, broken glass, poor housing, drug activity, violence, and a high prevalence of firearms in the hands of children, adolescents, and young adults.[36] In addition, children in low-income neighborhoods may have limited opportunities to engage in organized extracurricular activities. Other factors may operate at an individual or family level, such as supervision, knowledge, and education regarding child safety; access to safe and affordable child care; teenaged pregnancy; use of violence in response to conflicts; mental health; and stress. For risk factors that work at an individual level, the possibility of ecological fallacy[35,37] must be considered when the small-area approach is used.

TABLE 5—Injury Rate Ratios (RRs) in Moderately Low-Income and Largely Low-Income Census Tracts Relative to Rates in Referent Tracts

	Moderately Low-Income Tracts		Largely Low-Income Tracts	
	RR	95% CI	RR	95% CI
All injuries	1.7	1.6, 1.8	2.2	2.0, 2.4
Unintentional injuries	1.6	1.5, 1.8	2.0	1.8, 2.3
Assault injuries	2.6	1.9, 3.7	4.5	3.2, 6.5
Self-inflicted injuries	2.3	1.3, 4.1	1.9	1.0, 3.7
Injuries of undetermined cause	1.6	1.2, 2.2	1.8	1.2, 2.6
Motor vehicle injuries	1.9	1.6, 2.4	2.5	2.0, 3.2
Pedestrian injuries	2.0	1.5, 2.7	3.1	2.3, 4.2
Fall injuries	1.5	1.3, 1.8	1.9	1.5, 2.2
Gunshot injuries	2.4	1.5, 3.9	3.4	2.0, 5.7
Burn injuries	1.4	1.1, 1.8	1.6	1.3, 2.1

Note. Referent census tracts were those in the lower 25th percentile in proportion of low-income households (n = 19). Moderately low-income tracts = census tracts in the middle two quartiles in proportion of low-income households (n = 37); largely low-income tracts = census tracts above the 75th percentile in proportion of low-income households (n = 19). CI = confidence interval.

The proportions of variance in incidence rates explained by low income (0.15 to 0.36) appear modest relative to R^2s seen in small-area studies of other health outcomes.[14–17,22–24] The causes of injury are multifactorial and most cases may not be associated with economic disparities. Preventable injuries certainly occur to children across all social strata, although they appear to occur at a higher rate in poorer neighborhoods. An additional consideration is that a program to prevent childhood injuries was initiated in Central Harlem during the last 3 years covered by this study.[38] Methodological factors likely to have attenuated the observed effects are the presence of random measurement error in the variables of interest and the fact that coverage by the two study hospitals was lower in the more disadvantaged section of Northern Manhattan, Central Harlem (see Methods section), which also had the highest injury incidence. Although the rates were adjusted overall to take into account treatment in other hospitals, information was not available to make differential adjustments for incomplete case ascertainment by census tract.

Further research is needed to determine the extent to which the association between low-income neighborhood and pediatric injury risk is causal and to identify specific mechanisms and pathways. Prevention efforts, however, need not wait for further research. An immediate implication of the results presented here, along with findings on injury morbidity and mortality in other populations, is that programs, policies, and legislation for child injury prevention should target socioeconomically disadvantaged communities. Within low-income urban neighborhoods, efforts should focus on prevention of a wide range of intentional and unintentional causes of injury, including assaultive and suicidal behaviors, access to firearms, motor vehicle collisions (especially with pedestrians), falls, and burns. A model injury prevention program targeting many of these causes has been initiated in Central Harlem.[38] □

Acknowledgments

This research was supported by grants from the Centers for Disease Control (R49/CCR 202585 and R48/CCR 205055), the National Institute of Neurological Diseases and Stroke (R29 NS27971-03 and R29 NS27971-04), and the Robert Wood Johnson Foundation.

The authors would like to acknowledge Dr Margaret Heagarty for significant contributions to the design of the study and to data collection; Dr Jamal Naqvi for assistance with data collection for the Northern Manhattan Injury Surveillance System; Ms Louise Berenson of the New York City Department of Health for assistance with the death certificate data; and Drs Howard Andrews and Elmer Struening and an anonymous reviewer

for suggestions regarding the small-area analyses and content of the paper.

Child and Adolescent Drownings in Harris County, Texas, 1983 through 1990

Carla L. Warneke, MS, and Sharon P. Cooper, PhD

ABSTRACT

Objectives. This study described childhood drowning rates and circumstances in Harris County, a large metropolitan area in Texas, and compared case ascertainment between data sources.

Methods. Drowning rates among Harris County residents newborn through 19 years of age were calculated from death certificate data (1983 through 1989), and local childhood drowning hazards were described on the basis of medical examiner data (1983 through 1990). Cases from both sources were compared to determine sensitivity of sources.

Results. The drowning rate among Harris County residents newborn through 19 years of age was 3.8 per 100 000 person-years. The drowning rates among Blacks and Hispanics exceeded that of Whites by 56% and 19%, respectively. The majority of the 196 unintentional drownings occurred in swimming pools. Half of the pool drownings occurred in apartment pools and 33% in private home pools. The medical examiner logbook identified a slightly higher number of drownings than did death certificates. *International Classification of Diseases* external cause of death codes were of limited use in describing drowning circumstances.

Conclusions. Childhood drowning hazards not previously reported were identified, specifically hazards in apartment pools and those among Hispanic children. (*Am J Public Health.* 1994;84:593–598)

Introduction

Drowning is the second leading cause of unintentional injury fatalities among persons newborn through 19 years of age.[1] Drowning patterns vary by geographic area, depending on the local physical and social environment[2]; therefore, community drowning site and victim profiles are necessary to tailor prevention programs appropriate for that community.[3] The three objectives of this study were to determine rates of drowning among Harris County, Texas, residents newborn through 19 years of age, to describe victims and circumstances for child and adolescent drownings occurring in Harris County, and to compare case ascertainment of death certificates and medical examiner files.

Methods

The two data sources used for this study were the Texas Department of Health computerized death certificate file and the Harris County medical examiner files. Data from the death certificates were used to calculate drowning rates for Harris County residents, and data from the medical examiner files were used to describe victims and circumstances for drownings occurring in Harris County. Data from both sources were used to determine the sensitivity of each source for case ascertainment.

Texas computerized death certificate data were available for the years 1983 through 1989. Records for Harris County residents were abstracted from the death certificate file if the person was younger than 20 years of age and the cause of death was drowning. Drowning was defined according to the *International Classification of Diseases* ninth revision (ICD-9) external cause of death codes E830 (accident to water craft causing submersion), E832 (other accidental submersion or drowning in water transport accident), E910 (accidental drowning and submersion), E954 (suicide and self-inflicted injury by submersion), E964 (assault by submersion), and E984 (submersion undetermined whether accidentally or purposefully inflicted).[4]

Injury rates were calculated per 100 000 person-years. The numerators for Harris County rate calculations included only residents of Harris County. Harris County population estimates by age, sex, and race/ethnic group for each of the years 1983 through 1989 were obtained from the Texas Department of Health, Bureau of State Health Data and Policy Analysis.[5] For deaths coded E910 (unintentional drownings excluding boating-related drownings), Harris County resident drowning rates were compared with drowning rates from Texas and the United States. Texas drowning frequencies and annual population estimates were obtained from the Texas Department of Health, Bureau of State Health Data and Policy Analysis,[5] and US drowning frequencies and annual population estimates were obtained from the National Center for Health Statistics.[6] Age- and sex-adjusted rates were calculated with the 1980 US popu-

At the time of the study, both authors were with the School of Public Health, The University of Texas Health Science Center at Houston.

Note. CI = confidence interval.
[a]Drowning deaths were identified by death certificates coded with the *International Classification of Diseases* (ninth revision) external cause of death code E830, E832, E910, E954, E964, or E984.[4]
[b]Rate per 100 000 person-years; Harris County annual population estimates for 1983 through 1989 were used to calculate rates.[5]
[c]The 1980 US population newborn through 19 years was used as the standard.

lation younger than 20 years of age as the standard. In calculating 95% confidence intervals (CIs), a Poisson distribution was assumed.[7] For rate calculations, race/ethnic group was classified as Anglo (White), Black, or Hispanic. The Texas Department of Health used a computer program to identify Spanish surnames. All Whites with Spanish surnames were classified as Hispanics, and all Whites with non-Spanish surnames were classified as Anglos.

Drownings among persons younger than 20 years were ascertained through the Harris County medical examiner logbook for the years 1983 through 1990. Information concerning victim, site, and circumstance was recorded if the submersion injury *occurred in* Harris County. Drug screens consisted of the urine enzyme-multiplied immunoassay technique (EMIT) screen; positive results were confirmed by ultraviolet spectrometry, mass spectrometry, thin-layer or gas chromatography, or a combination of these. Blood alcohol concentrations were recorded in percentage weight of alcohol per 100 mL of blood. Blood alcohol determinations were considered valid estimates of blood alcohol at time of injury if the individual survived less than 6 hours after submersion and was tested within 24 hours of death.[8]

The computerized death certificate file does not indicate county of submersion injury, but it does list county of death. Therefore, to determine case ascertainment of each data source, drownings among persons newborn through 19 years of age for whom the county of death was Harris County were ascertained from death certificates and from the medical examiner logbooks for the years 1983 through 1989.

The cases from each source were matched on the decedent's date of death, date of birth, age, sex, and residence. Sensitivity was computed for each method of case ascertainment as [cases identified/(cases identified + cases missed) × 100].[9] Death certificate records for cases identified only through the medical examiner logbook were sought by searching the computerized death certificates for a case in which the decedent had the same age, race, sex, residence, date of birth, and date of death as the decedent in the case from the medical examiner file. The medical examiner logs were reexamined in an attempt to locate cases ascertained only by the death certificate file.

Results

Death certificates identified 243 drownings during the years 1983 through 1989 among Harris County residents newborn through 19 years. The county of death was Harris County for 72% of the residents. The remainder died out of state (2%) or in 17 other Texas counties (26%). The crude drowning rate for Harris County residents younger than 20 years was 3.8 per 100 000 person-years (95% CI = 3.3, 4.3), and the age- and sex-adjusted drowning rate was 3.7 per 100 000 person-years (95% CI = 3.3, 4.2).

Drowning rates varied between age groups. Rates were highest among children younger than 5 years (Table 1). The age-adjusted drowning rate for males was 2.9 times higher than the rate for females. The highest drowning rate was for females younger than 1 year. For all other age groups, the rate of drowning for males exceeded the rate for females. Drowning rates varied by race/ethnic group: the age- and sex-adjusted rate per 100 000 person-years for Blacks (5.0; 95% CI = 3.8, 6.4) was 56% higher than that for Whites (3.2; 95% CI = 2.7, 3.9), and the rate for Hispanics (3.8; 95% CI = 2.9, 4.9) was 19% higher than that for Whites. The age-adjusted drowning rate for each sex was highest for Blacks (Table 2).

For drownings coded E910 (unintentional drownings excluding boating-related drownings), age- and sex-adjusted rates per 100 000 person-years in Harris County (3.5; 95% CI = 3.1, 4.0) exceeded the rates for Texas (3.3; 95% CI = 3.1, 3.5) and the nation (2.5; 95% CI = 2.5, 2.6).

For the years 1983 through 1990, the medical examiner logbook identified 214 drownings among persons newborn through 19 years for whom the site of submersion was Harris County. The county of residence in 92% of the cases was Harris County. The nonresidents were from nine other Texas counties (n = 10) and out of state (n = 8). One third of the drowning victims were declared dead at the site of injury.

Files for all cases were retrieved with the exception of one case that had

apparently been misfiled. Limited information available from the medical examiner logbook was used for this case. Deaths were unintentional in 96% (n = 196) of the cases, homicidal in 2% (n = 4), and of undetermined intent in 2% (n = 5). In addition, there were nine newborns who drowned as a result of being delivered into the toilet or bathtub. These birth-related drownings are discussed separately.

Unintentional Drownings

Medical examiner logs identified 196 unintentional drownings. The annual number of unintentional drownings varied from a high of 31 in 1983 to a low of 19 in 1989; however, this variation does not represent a consistent decline in the number of drownings over the 8-year study period. Of the 187 drownings for which the month of injury was known, 81% occurred in the months April through September. Of the 180 cases for which the day of injury was known, drownings occurred most frequently on Sunday (n = 41) and Monday (n = 36).

The age groups with the highest frequency of drownings were children younger than 5 years of age (n = 108) and teenagers 15 through 19 years of age (n = 42). Seventy-four percent of unintentional drowning victims were male. Forty-seven percent of unintentional drowning victims were White, 28% were Black, and 25% were Hispanic. Of the 162 cases in which information on witnesses was reported, 63% of the submersions were not witnessed. The site of submersion was recorded for 192 of the unintentional drownings; 55% occurred in swimming pools or hot tubs, 13% occurred in bathtubs, 3% occurred in buckets or toilets, and 29% occurred in other bodies of water. Drownings in other bodies of water were most frequently witnessed (73%).

Swimming pools and hot tubs. There were 102 drownings in swimming pools and 4 drownings in hot tubs. The children who drowned in hot tubs were aged 16 to 34 months. The children who drowned in pools were most frequently 1- or 2-year-olds.

Swimming pools were the site of the highest percentage of drownings for all age groups under 15 years (Figure 1) and for all race/ethnic groups. Pool drownings occurred in apartment pools (50%), private home pools (33%), public/school pools (11%) and motel/hotel pools (5%). The type of pool in which the drowning occurred varied by race/ethnic group. Drownings among Whites most frequently occurred in private home pools, and drownings among Blacks and Hispanics most frequently occurred in apartment pools.

Together, private home pools and apartment pools represented 91% of pool drownings among preschoolers (children younger than 5 years of age). Among preschoolers, 68% of private home and apartment pool drownings occurred at the home of the decedent, and the remaining 32% occurred at the home of a relative, friend, or neighbor or at a vacant home. Information regarding fencing was seldom recorded and was often incomplete.

Bathtubs. Twenty-five unintentional drownings occurred in the bathtub. Bathtubs were the site of drowning for 33% (n = 17) of the females, compared with 6% (n = 8) of the males. Hispanics (n = 14) drowned in bathtubs at a frequency more than twice that of Whites (n = 6) or Blacks (n = 5). Forty-eight percent of the children who drowned in the bathtub were aged 6 to

TABLE 2—Race- and Sex-Specific Drowning Rates per 100 000 Person-Years for Harris County, Texas, Residents Newborn through 19 Years of Age, 1983 through 1989

	White		Black		Hispanic	
	Females	Males	Females	Males	Females	Males
No. cases[a]	33	83	17	48	16	46
Crude rate[b]	1.97	4.76	2.45	6.87	2.03	5.48

[a]Drowning deaths were identified by death certificates coded with the *International Classification of Diseases* (ninth revision) external cause of death code E830, E832, E910, E954, E964, or E984.[4]
[b]Rate per 100 000 person-years; Harris County annual population estimates for 1983 through 1989 were used to calculate rates.[5]
[c]The 1980 US population newborn through 19 years was used as the standard.

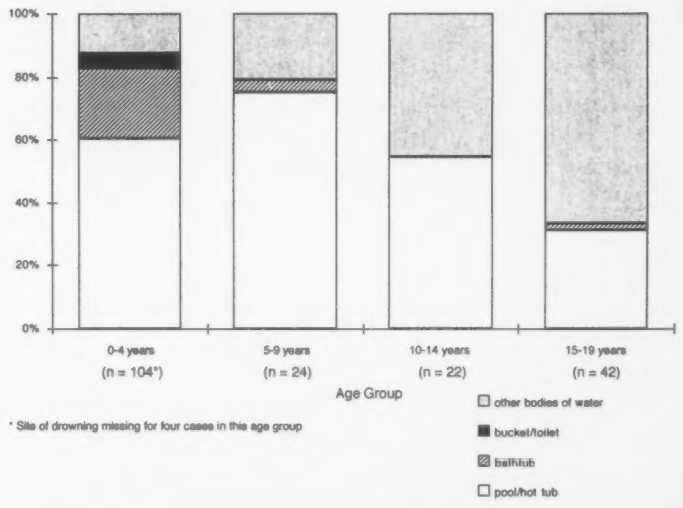

FIGURE 1—Percentage distribution for location of submersion, by age group, for unintentional drownings that, according to medical examiner files, occurred in Harris County, Texas, 1983 through 1990, among persons newborn through 19 years.

TABLE 3—Drugs Detected at Autopsy[a] in Persons Newborn through 19 Years of Age Who Drowned in Harris County, Texas, 1983 through 1990

Drug Category	No. Persons[b]	% of Persons Testing Positive	Drug Detected	
			Frequency	Name
Not likely to be a causal factor in drowning	10	40	2	Acetaminophen (Tylenol)
			3	Caffeine
			1	Ibuprofen
			12	Nicotine
Likely to have been hospital administered	9	36	4	Lidocaine
			3	Phenobarbital
			2	Phenytoin
			1	Thiopental sodium (Pentothal sodium)
Could alter functions needed to prevent injury	6	24	1	Amitriptyline (Elavil)
			1	Cocaine
			1	Codeine
			2	Diazepam (Valium)
			1	Inhalants
			1	Methylene-dioxy-methamphetamine (ecstasy)
			3	Tetrahydrocannabinol (marijuana)

Note. Data were taken from the Harris County medical examiner files.
[a]The medical examiner autopsied or viewed 203 decedents and performed drug screens on 153 decedents. Twenty-five persons tested positive for at least one drug.
[b]Some persons tested positive for more than one drug.

11 months. The two persons older than 4 years of age who drowned in bathtubs had epilepsy or a physical handicap. In 9 cases the child was bathing alone; in 10 cases the child was bathing with someone else, most often one or two preschool-aged children; and information was missing in the remaining 6 cases. Twenty of the children were bathing or playing in the bathtub at the time of injury, three children fell into water left standing in the bathtub, and the activity of two children prior to drowning was not mentioned.

In all cases in which information on supervision was available (n = 23), a lapse in supervision was reported. The length of the lapse was mentioned in 15 cases and ranged from "a few seconds" to 15 minutes, usually 5 minutes or less. The reasons for the lapse were most commonly answering the telephone, performing household chores, or dressing.

Small containers. Four unintentional drownings occurred in buckets, and one drowning occurred in a toilet. All five children were aged 9 to 16 months. The buckets were typically 5-gallon buckets containing water with cleaners used for mopping.

Other bodies of water. Fifty-six unintentional drownings occurred in other bodies of water: rivers (n = 13), bayous (n = 12), lakes (n = 10), ponds or sandpits (n = 6), ditches or irrigation canals (n = 6), creeks (n = 5), and other water sources (n = 4). Eighty-nine percent of these drowning victims were male, and 50% of the drownings occurred to persons aged 15 through 19 years.

Motor vehicle incidents contributed to two drowning deaths, and one drowning resulted from a boating incident. Of the 45 cases in which activity prior to submersion was reported, 42% of the persons were intentionally in the water at the time of injury, 2% drowned during an attempt to rescue another drowning person, 9% were boating or rafting, and 47% did not intend to enter the water. In half of the cases depth of the water (from 5 inches to 25 feet) was mentioned. Information on personal flotation devices was seldom recorded.

Birth-Related Drownings

Medical examiner files identified nine newborn drownings resulting from delivery into the toilet or bathtub. Five of these drownings were unintentional, two were intentional, and two were of undetermined intent. Seven of the nine newborns were Black, one was White, and one was Hispanic. Two of the newborns were premature, and in six cases the mother reported that she did not know she was pregnant before delivery. In three of these cases the mother was living at home with her parents, who also stated that they were unaware of their daughter's pregnancy.

All Drownings

Alcohol and other drugs. Of the 214 cases identified from the medical examiner files, 203 drowning victims were autopsied or viewed, and 84% of these were tested for alcohol, drugs, or both. A blood alcohol analysis was performed on 165 victims, 112 of which met the specified criteria for result representative of blood alcohol concentration at the time of injury. Five of the 112 tested positive, with blood alcohol concentration levels 0.03, 0.04, 0.13, 0.18, and 0.25 g/mL. All positive determinations were for males aged 18 or 19 years. Seventeen other victims tested positive for alcohol; however, in these cases, the representativeness of blood alcohol concentration at time of death either could not be determined or was invalid.

Drug screens were performed on 153 victims, 16% of whom tested positive for at least one drug. When drug screens positive only for drugs that were unlikely to contribute to drowning or drugs that were most likely administered by hospital personnel were eliminated, six persons tested positive for a drug that could have contributed to drowning (one person was also positive for alcohol) (Table 3). With the exception of a newborn who tested positive for diazepam, all persons testing positive for drugs that could have contributed to their deaths were males aged 17 through 19 years. Thirty-five percent (n = 9) of all drownings among 17- through 19-year-old males (n = 26) were drug or alcohol related.

Antecedent medical problems. In 16 cases, antecedent medical problems other than substance use were noted. Three persons experienced acute head injury immediately prior to drowning. One injury resulted from a motor vehicle incident, and two resulted from the individual's hitting his head on the pool while diving or swimming. Eight persons had a history of epilepsy or seizure disorder; four of these were also mentally handicapped. A total of six drownings involved the mentally handicapped. Three drowning victims had other physical handicaps (one was blind, one was

deaf, and one was a quadriplegic as a result of cerebral palsy).

Data Source Comparisons

For the years 1983 through 1989, drowning deaths that occurred in Harris County, regardless of county of submersion, were ascertained from both the medical examiner records and the computerized death certificates. Together, the data sources identified 222 cases. The medical examiner logbook search ascertained 213 cases for a sensitivity of 96%, and the computerized death certificate search ascertained 208 cases for a sensitivity of 94%.

Of the 14 cases identified only by the medical examiner logbook, no death certificate could be identified for 3 (2 homicides and 1 undetermined intent), and 11 were assigned a death certificate ICD-9 code for a cause of death other than drowning: E908.0, weather-related death (n = 3); 345.9, epilepsy (n = 2); E815.0 and E816.0, motor vehicle accident (n = 2); E901.8, accident due to excessive cold (n = 1); 335.0, Werdnig-Hoffman disease, or infantile spinal muscular atrophy (n = 1); 348.1, anoxic brain damage (n = 1); and 348.5, cerebral edema (n = 1). The nine cases identified only by the death certificate file had cause of death codes E830, accident to watercraft causing submersion (n = 1); E910, unintentional drowning (n = 7); and E964, homicide (n = 1).

E-codes were of limited use for determining the circumstances of the drowning. E-codes agreed with the medical examiner data concerning intent of injury in all but one case; however, analysis of E-codes did not describe location or activity of the victim at the time of submersion (Table 4).

TABLE 4—E-Codes Assigned to Death Certificates Compared with Site of Drowning Recorded by Harris County Medical Examiner for Unintentional Drownings of Persons Newborn through 19 Years of Age Who Died in Harris County, Texas, 1983 through 1989

Death Certificate File[a]		Medical Examiner File						
		Boating	Bath	Hot Tub	Pool	Other	Bucket	Total
E830	Accident to watercraft causing submersion	1	...	...	...	...	...	1
E910.4	Accidental drowning or submersion in bathtub	...	1	2	...	...	...	3
E910.8	Other accidental drowning or submersion including drowning in quenching tank or swimming pool[b]	...	26	2	91	50	7	176
E910.9	Unspecified accidental drowning or submersion including fall into water not otherwise specified and drowning not otherwise specified	...	...	...	4	2	...	6
Total		1	27	4	95	52	7	186

Note. Table excludes five cases for which place of injury was unspecified in the medical examiner file.

[a]E-codes are *International Classification of Diseases* (ninth revision) external cause of death codes.[4]

[b]There were no drownings coded E910.0, accidental drowning or submersion while water skiing; E910.1, accidental drowning while engaged in other sport or recreational activity with diving equipment; E910.2, accidental drowning or submersion while engaged in other sport or recreational activity without diving equipment; or E910.3, accidental drowning or submersion while swimming or diving for purposes other than recreation or sport.

Discussion

Among persons younger than 20 years, risk groups for drowning in Harris County, Texas, were similar to those reported in other studies on drowning.[2,10,11] However, a unique finding of this study was that 50% of pool drownings occurred in apartment pools and 33% occurred in private home pools. Most studies have reported that the majority of drownings in pools occurred in private home pools and have not specifically addressed apartment pools.[2,12–14] An exception is a study in King County, Washington, that reported that 22% of the drownings in pools occurred in apartment pools and 37% occurred in private home pools.[3] Further study is needed to determine whether the large percentage of drownings in Harris County apartment pools is explained by the high prevalence of apartment pools in Harris County or by some other factor affecting the safety of the apartment pools.

Drowning prevention is the most effective method for reducing the number of drownings. Although postsubmersion interventions are crucial, one third of the persons who drowned in Harris County never reached the hospital for treatment. Furthermore, survivors of a submersion injury can suffer serious neurologic damage, which can be physically, psychologically, and financially devastating to the child and the child's family.[15]

Individual and societal interventions are two approaches to drowning prevention. Individual interventions include education of the child and the child's supervisor. A national survey of parental knowledge of injury prevention indicated that parents consistently underestimated the risk of drowning to children and that they lacked knowledge about risk reduction beyond "being careful."[16] A survey of pool owners in California found that the proportion of the population endorsing risk reduction measures, such as four-sided fencing of pools, greatly exceeded the proportion who adopted safety measures.[17] This gap between knowledge and practice supports the utilization of social interventions such as legislation for effective pool drowning prevention programs, with health education as a useful adjunct. For each age group and drowning site in the present study, the events that led to drowning were diverse and would require different preventive approaches.

Ascertainment of drowning deaths was similar for both data sources. The medical examiner logs were slightly more sensitive than the death certificate file for identifying drownings, but analysis of medical examiner data, which are not computerized in Harris County, is more time-consuming than analysis of the computerized death certificates. It is possible that both methods of ascertainment missed cases, especially cases in

which persons survived for a period of time to die later of secondary complications. Severely brain-damaged victims have an average life span of 12 to 18 months.[15] If the date of death was more than 1 year from the time of injury, the cause of death should be coded on the death certificate as E929.8, late effects of accidental injury;[4] therefore, such a case would not be included in the death certificate analysis of drownings.

The computerized death certificates were of limited use because of their brevity as well as coding methods. Analysis of the effect of interventions such as mandatory four-sided fencing for pools would not be possible with E-codes, because no specific code exists for pool drownings. Although the medical examiner files were more useful than the computerized death certificates for collecting detailed information on drowning, much of the information needed to evaluate current prevention efforts was missing or included only sporadically. A more systematic data collection method is needed to provide the information necessary to accurately evaluate the effectiveness of established and proposed prevention efforts.

Both data sources ascertained deaths, which represent only a portion of submersion injuries. Studies have estimated that there are from 4 to 18 near-drownings per drowning[3,11,18] and that 6% to 16% of near-drowning survivors suffer from brain damage.[3,18,19] Without information on near-drownings, it is not possible to identify causes of trends in drowning. A decrease in the number of drownings could reflect a real decrease in the number of submersion events, or it may mean that improvements in medical technology or emergency medical services have enabled more of those with submersion injuries to recover intact or with neurologic damage. Surveillance of injury incidence and outcome is needed to monitor current prevention efforts and to assess both individual and societal costs of submersion injury.

Although this study provided potentially useful data concerning victims and circumstances of drowning in Harris County, the study was limited by factors inherent to a descriptive study design. An analytic study design is required to test hypotheses concerning drowning determinants and drowning prevention. Areas needing further investigation are many and include drownings in apartment pools, drownings among Blacks and Hispanics, the effects of swimming lessons on drowning rates, the reduction of alcohol use in aquatic settings among teenaged males, factors influencing adolescents' voluntary use of life vests, the relationship between socioeconomic status and drowning, and the risk of drowning among children with disabilities. In addition, data on the outcome of near-drowning incidents are needed to fully describe the impact of submersion injuries and to evaluate prevention efforts. □

The Effects of Recall on Estimating Annual Nonfatal Injury Rates for Children and Adolescents

Yossi Harel, PhD, Mary D. Overpeck, DrPH, Diane H. Jones, PhD, Peter C. Scheidt, MD, MPH, Polly E. Bijur, PhD, MPH, Ann C. Trumble, PhD, and John Anderson, PhD

ABSTRACT

Objectives. This study used a recent national population survey on childhood and adolescent nonfatal injuries to investigate the effects of recall bias on estimating annual injury rates. Strategies to adjust for recall bias are recommended.

Methods. The 1988 Child Health Supplement to the National Health Interview Survey collected 12-month recall information on injuries that occurred to a national sample of 17 110 children aged 0 through 17 years. Using information on timing of interviews and reported injuries, estimated annual injury rates were calculated for 12 accumulative recall periods (from 1 to 12 months).

Results. The data show significantly declining rates, from 24.4 per 100 for a 1-month recall period to 14.7 per 100 for a 12-month recall period. The largest declines were found for the 0- through 4-year-old age group and for minor injuries. Rates of injuries that caused a school loss day, a bed day, surgery, or hospitalization showed higher stability throughout recall periods.

Conclusions. Varying recall periods have profound effects on the patterns of childhood injury epidemiology that emerge from the data. Recall periods of between 1 and 3 months are recommended for use in similar survey settings. (*Am J Public Health.* 1994;84:599–605)

Introduction

Injuries have emerged as the principal threat to the health and well-being of children and adolescents. Knowledge of the distribution and determinants of nonfatal injuries in childhood is critical for the development and evaluation of intervention strategies. Population-based surveys are needed to calculate annual injury rates for different subpopulations and/or for different types of injuries. Estimates of nonfatal injury rates in the United States have been based on 2-week recall information obtained from representative samples of households.[1–5] Information ascertained retrospectively through self-reports or proxy reports about exposures or health outcomes may be subject to bias due to differential recall patterns.[6–11] There are two main reasons for recall bias: (1) memory decay—the loss of information due to failure to recall the event, and (2) the "telescoping effect"—the tendency to remember events in the past as if they occurred closer to the present than they really did. Recall bias tends to increase with the enlargement of the recall period inherent in the survey questions.

Since 1957, the National Center for Health Statistics has collected information about injury episodes on the basis of a 2-week recall period.[12] Injuries are identified by asking about reasons for doctor visits or restricted activities within the previous 2 weeks.[3–5] Estimates of annual injury rates are then calculated by multiplying the number of injuries reported for the 2-week recall period by 26 to obtain a 12-month estimate of the numerator. This method may cause the overestimation of injury rates due to telescoping and the magnification of the introduced error by multiplying the number of injuries by 26 to annualize the rate. In addition, the low frequency of injuries in the 2 weeks prior to the interview limits the association of injury with an individual's characteristics. The National Health Interview Survey (NHIS) uses a 2-week recall period for acute conditions because information is lost from failure to remember events over longer periods. Consequently, any attempt to analyze individual or family determinants of injury outcomes based on 2-week recall requires aggregation of data across several years of NHIS surveys to obtain a sample size sufficient for statistical power.

The 1988 Child Health Supplement (CHS) to the NHIS collected information on the occurrence of childhood injuries from an adult respondent, usually the mother. The survey provides the first population-based national data on nonfatal injuries to assist public health

At the time of the study, Yossi Harel was a Visiting Scientist at the Centers for Disease Control and Prevention, Atlanta, Ga, and at the National Institute of Child Health and Human Development, Bethesda, Md. Mary D. Overpeck, Peter C. Scheidt, and Ann Trumble are with the National Institute of Child Health and Human Development, Bethesda, Md. Diane H. Jones and John Anderson are with the Centers for Disease Control and Prevention, Atlanta, Ga. Polly E. Bijur is with the Albert Einstein College of Medicine, Bronx, NY.

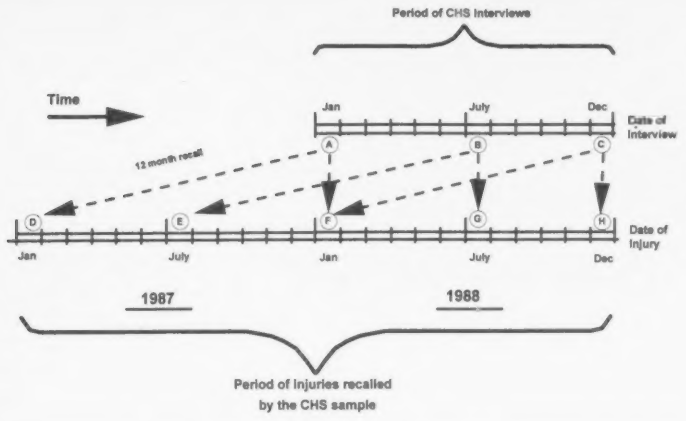

FIGURE 1—Timing of Child Health Supplement interviews and corresponding injury recall periods.

agencies in determining policy objectives and priorities. The NHIS CHS used a 12-month recall period for obtaining information about medically attended injuries rather than the usual 2-week recall period. This longer recall period is likely to produce lower annual estimates than shorter recall periods, owing to memory decay, but may produce higher frequencies of injuries for analysis. The choice of the most appropriate recall period is based on balancing the need for reliable and accurate information with the need for an adequate number of injuries in the data to provide sufficient statistical precision and power.

The purpose of this study was to analyze the effects of using different recall periods on estimated annual injury rates for various subpopulations and for different types of injuries. In so doing, we evaluated the magnitude of the bias and determined the most reliable approach for analysis and interpretation with respect to the recall periods involved.

Methods

Source of Data

The NHIS is a representative sample of the US civilian noninstitutionalized population.[5] The survey collects information about social and economic characteristics, acute and chronic conditions, restricted and limited activity, and physician contacts or any other health care utilization. The 1988 NHIS sample was completed in 47 485 households containing 122 310 persons, 94.9% of whom completed the interviews.[1]

The CHS was added to the core NHIS for the period January 1988 to January 1989 and was designed to produce a representative sample of US children from 0 through 17 years of age. One child in each household with children in the eligible age range was selected, resulting in a sample of 17 110 completed interviews. The information was obtained by face-to-face interview with a responsible adult in the household, usually the child's mother. The survey included such topics as parental history, birth history, school and day care experiences, developmental and behavioral problems, acute and chronic childhood conditions, and other information including a detailed set of items on occurrences of accidents, injuries, and poisonings. Additional information on the methods and design of the 1988 NHIS and CHS surveys is reported elsewhere.[1]

Operational Definition of an Injury

Two screening questions were used: (1) "During the past 12 months, did ____ have an accident, injury, or poisoning that required medical attention?" (2) "How many accidents, injuries, or poisonings did ____ have in the last 12 months that required medical attention?" Beginning with the most recent injury, the respondent was asked to answer questions about the timing and cause of the injury, the place where it happened, the nature of the injury, and restriction of activity, doctor visits, and hospitalizations that resulted from the injury. Information was collected for each of up to 11 injuries reported.

Injuries occurring prior to the recall period that resulted in chronic conditions were not included. Injuries resulting from misadventures or complications of medical care (*International Classification of Diseases* E codes 870–879[13]) were excluded from the analyses. Also excluded were secondary conditions that resulted from injuries already accounted for in a previous injury report.

Timing of the Injury Episode

Interviews were evenly distributed throughout the 1988 calendar year and constituted a nationally representative sample for each individual month of interview. Figure 1 presents the relationship between the date of the interview and the timing of the reported injury. For example, an individual interviewed in January of 1988 (A) may report an injury that occurred within the same week as the interview (F) or an injury that occurred in January 1987, 12 months prior to the interview (D). On the other hand, an individual interviewed 1 year later, in late December of 1988 (C), may report an injury in the same week as the interview (H) or an injury 12 months earlier, in January of 1988 (F). The array of injury events reported for a 12-month recall period covers a calendar period of 2 full years, from January 1987 through December 1988.

To assess the bias resulting from estimates based on different recall periods, the amount of time elapsed between the occurrence of a reported injury and the timing of the interview must be known. Thus, the following timing question was added: "In what month and year did the accident, injury, or poisoning occur?" With information on the month and year in which both the injury and the interview took place, the time interval between the two events can be calculated.

The timing item was added to the CHS instrument only for the last two quarters of the annual sample (i.e., for those interviews occurring between July and December 1988). The respondents interviewed in July 1988 (B) reported recall of injuries occurring in the preceding 12 months, or from July 1987 (E) through July 1988 (G). Similarly, those interviewed in late December 1988 (C)

reported injuries occurring from January 1988 (F) through December 1988 (H). Thus, these data reflect seasonality over a 1.5-year period (from E through H). The present study is based on timing information available for the latter two quarters of the sample. The NHIS sampling technique ensures that the two quarters of available data provide a nationally representative sample.

Calculation of Recall Intervals

The smallest time unit for which timing of the interview and timing of the injury exists is a 1-month period. Therefore, recall time intervals are calculated by subtracting the calendar month of the injury from the interview month. The timing of an interview or the injury event was assumed to be the midpoint of the month in the reporting month. On the basis of this assumption, each calculated interval actually covers a potential recall period of 2 full months.

To illustrate, say an interview that took place in May 1988 reported an injury occurring in April 1988. In this case, the recall interval is calculated as 1 month. However, the sample might include an injury event occurring on April 30 and an interview on May 1, the following day, and a second injury event on April 1 reported from an interview on the last day of May. Despite the fact that the actual time gap between the injury and the interview was only 1 day in the first case and almost 2 months in the second case, both cases represent a 1-month recall period.

The recall period time interval scale involves 12 scores—a score of 1 represents a recall period of 1 day to 2 months, a 2 represents a period of 1 to 3 months, and so on up to a score of 12, which represents a recall period of 11 to 13 months prior to the interview. From a mathematical point of view, this method of calculation creates a smoothing effect between the time-interval scores by virtue of the 1-month overlap between intervals that minimizes random fluctuations occurring between months of interview.

Injuries reported during the calendar month in which the interview took place resulted in a score of 0 months elapsed between the month of the injury and the month of the interview. This interval is incompatible with the other 12 timing categories. First, it covers half the time range covered by other recall intervals (a mean period of only 2 weeks), and second, it results in a range that includes a 12.5-month period. This problem is resolved by adding the injuries with a timing duration of 0 to those reported in the first month. Assuming that both the interviews and the injuries in the 0-month period occurred at the midpoint of the month, the combined 0- and 1-month period is 6 weeks. Therefore, the combined number of reported injuries was multiplied by the proportion of 1.5 months out of a year. Since all subsequent recall periods include the events from the 0-month category in their respective numerators, the multiplier was calculated as follows:

$$12/(j + 0.5),$$

where j = the months elapsed between the injury and the interview. This solution is frequently used in the calculation of life tables. Smith, for example, describes a life-table method in which events occurring in the same month as the interview are excluded from the life tables.[14]

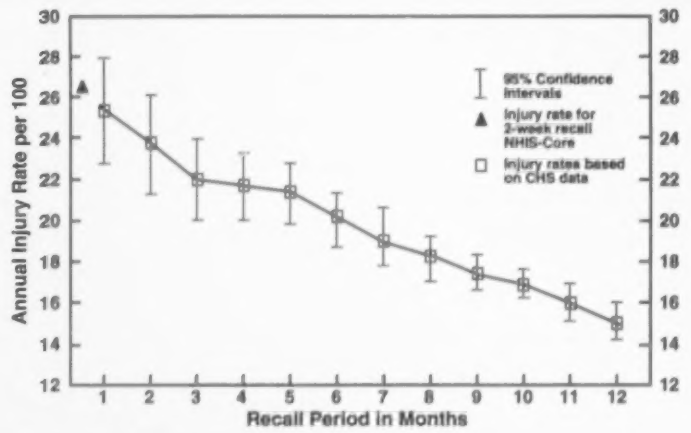

FIGURE 2—Estimated annual injury rates, by recall period, for all children 17 years of age and younger.

Calculating Estimates of Annual Injury Rates per Recall Interval

Weighted annual rates were calculated for recall periods ranging from 1 to 12 months in 1-month increments. Estimated annual injury rates based on a specific recall period are based on the weighted number of injuries reported for that period multiplied by the proportion of the year represented by that recall period and divided by the weighted total number of respondents in the subsample of interest. A constant of $K = 100$ was used to obtain estimated rates per 100 children in the population. Note that the recall periods are mutually inclusive so that a 2-month period, for example, includes the 1-month period. Identical calculations were repeated for different age and sex groups and for different types of injuries. All calculations were carried out using appropriate personal weights. SESUDAAN linear regression methodology was used to calculate 95% confidence intervals for each estimated rate.[15] Approximately 9% of injuries had missing data codes on the timing of the event and thus were not included in the calculation of the numerators for the recall period–specific rates. To maintain the most accurate representation of rates, the data were adjusted for missing data by adding the relative proportion of the injuries with missing data on timing to each recall period–specific rate.

Results

A total of 2854 injuries occurred during the entire survey year. Complete data on 2773 injuries resulted in a total annual injury rate of 16.3 injury episodes per 100 children from 0 through 17 years of age. Of all children reported by their parents to have sustained injuries, 347 (14.9%) had more than one injury. All subsequent results presented here are based on the latter two quarters of the sample for which timing injury information was available.

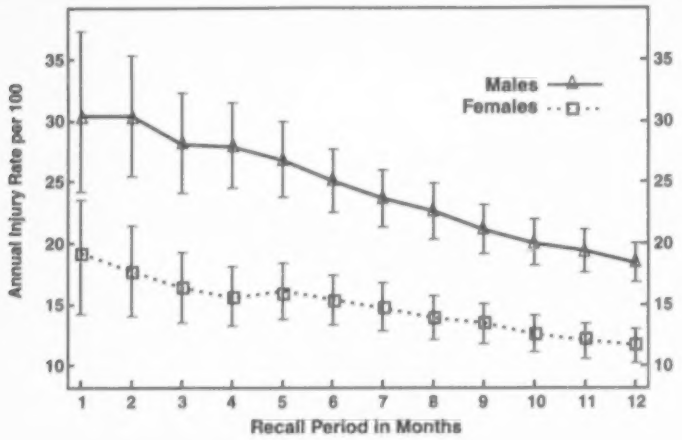

FIGURE 3—Sex-specific estimated annual injury rates, by recall period.

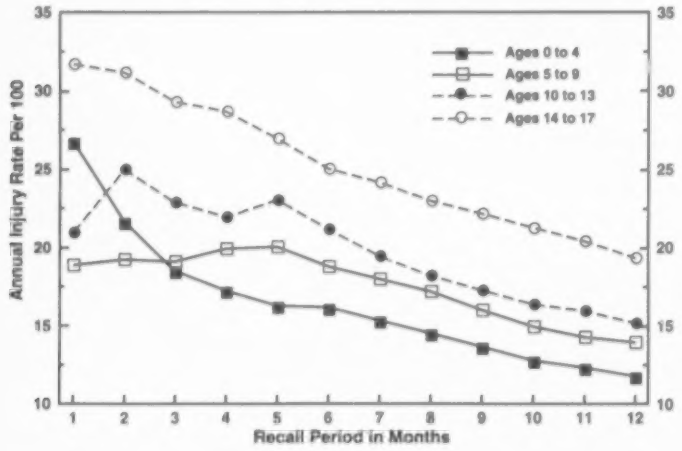

FIGURE 4—Age-specific estimated annual injury rates, by recall period.

Analyses of Recall Bias

Figure 2 shows weighted annual estimated injury rates for all 12 recall periods. These data show a substantial linear decline of the estimated annual rates, from 24.4 per 100 for a 1-month recall period to 14.7 per 100 for a 12-month recall period. The black triangle at top left of the figure represents the 26.4 per 100 injury rate based on a 2-week recall period that most closely approximates the inclusion criteria used in the CHS data (namely, injuries defined as acute conditions, onset during the past 2 weeks, first injury per injury episode, not an adverse effect of medical care, and no doctor visit more than 2 weeks ago). Rates calculated for longer recall periods are based on a larger number of observed injuries in the numerator compared with rates calculated for shorter recall periods. Thus, the confidence intervals are larger for short recall periods and smaller for longer recall periods.

These results demonstrate the critical importance of the length of the recall period in calculating an estimate of injury rates for children. According to these findings, the incidence of injuries among American children can vary from one injury in three children per year, based on a 2-week recall period, to one injury in seven children per year, based on a 12-month recall period.

The results in Figure 2 raise two questions: (1) What are the characteristics of the injuries that tend to be underreported as the recall period is increased? and (2) What are the characteristics of the injuries that tend to be remembered and reported even at 12 months? To answer these questions, we repeated the analyses for different sex and age groups and for injuries of different severity.

Differences in Recall Patterns by Sex

Figure 3 presents estimated annual injury rates per recall period interval by sex. The rates for boys are significantly higher than those for girls for all recall periods. Boys' rates show a sharper decline, from 30 per 100 for a 1-month recall period to about 18 per 100 for a 12-month recall period. A similar slope is shown for girls, whose rates decline from about 17.5 per 100 for a 1-month recall period to about 11 per 100 for a 12-month interval. In both cases, the amount of decline represents about 40% of the rate calculated for the 1-month recall interval.

Differences in Recall Patterns by Age Group

The data presented in Figure 4 show marked differences in recall decline among children in different age groups. Adolescents' rates decline from approximately 32 per 100 for a 1-month recall period to about 19 per 100 for a 12-month recall period. The slope of decline is stable across the 12-month period. The recall of injuries for children aged 5 through 9 and 10 through 13 years is stable for the first 5 months of the recall intervals. However, a remarkable finding is the sharp fall of estimated annual rates for children from 0 through 4 years of age, from a rate of about 27 per 100 for a 1-month recall period to a rate of about 16 per 100 for a 5-month recall period—a fall of over 70% of the decline for the total 12-month period.

Age-specific patterns of recall may differ for boys and girls. To investigate this possibility, we repeated the age-specific analyses for boys and girls separately. The results for age groups

younger than 13 years show similar slopes by sex, despite significant differences in the magnitude of the injury rates between the two sex groups. For adolescents aged 14 through 17 years, the recall of injuries among females appears to be stable across recall intervals, compared with the significant decline found among males. This difference is due, in part, to the difference in the magnitude of rates for adolescents by sex and to the larger number of injuries to be remembered or forgotten by mothers of adolescent boys compared with the smaller number of injuries sustained by girls. Yet the decline for adolescent boys remained sharp and linear across the 12-month period.

Differences in Recall by Type of Injury Severity Measure

Figure 5 presents estimated annual injury rates by recall intervals for three types of injury severity measures: (1) injuries resulting in surgery or hospitalization (i.e., severity based on medical treatment); (2) injuries resulting in at least 1 full bed day or 1 full school loss day (i.e., severity based on restriction of activity); and (3) injuries that did not result in any of the above consequences (i.e., minor injuries). Note that the first two severity types are not mutually exclusive; however, minor injuries are exclusive of the other two types.

As expected, minor rates decline linearly in magnitude, from 17.5 for a 1-month recall period to about 10 per 100 for a 12-month recall period. On the other hand, patterns are stable for both types of severity of injuries. Injuries that resulted in a doctor visit (not shown in Figure 5) show a slope very similar to that of minor injuries, indicating that reported doctor visits do not explain the variation in recall.

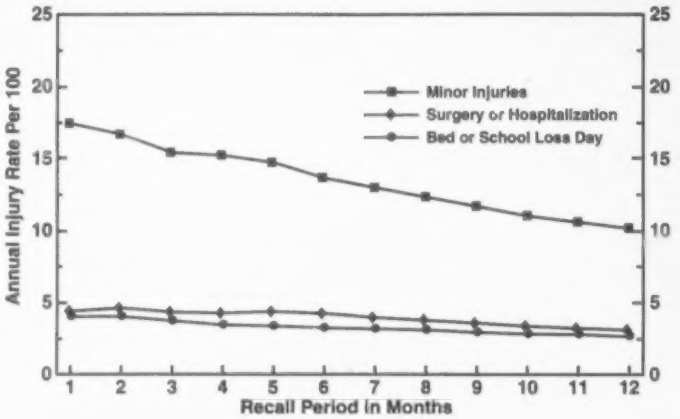

FIGURE 5—Estimated annual injury rates, by severity and recall period.

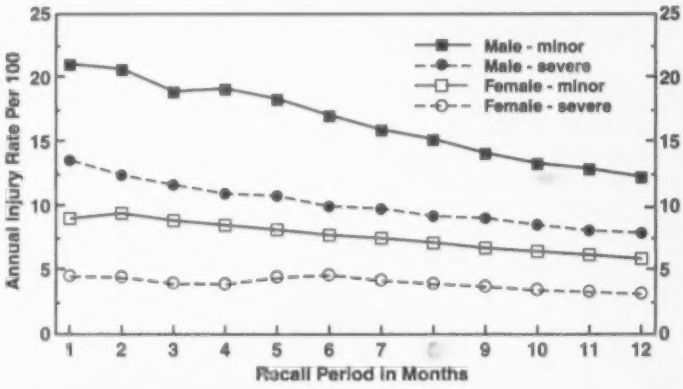

FIGURE 6—Sex-specific estimated annual injury rates, by severity and recall period.

Recall of Age- and Sex-Specific Injury Rates by Injury Severity

To investigate the possibility that the recall differences found for sex and age groups reflect severity differences in the pattern of injuries sustained, we examined sex- and age-specific injury rates for different measures of injury severity by recall periods. Based on the results presented in Figure 5, we constructed a dichotomous measure of injury severity. Injuries resulting in at least 1 bed day, 1 school loss day, surgery, or hospitalization were defined as severe injuries. All other injuries were defined as minor injuries. Figure 6 contrasts the results for minor and severe injuries. Minor injuries have a stronger decline in injury rates across the recall periods for both boys and girls. Minor injury rates for both sexes show similar slopes of decline across the recall periods. However, severe rates appear to be more stable across recall periods for girls than for boys.

Figure 7 shows that severe rates are more stable than minor rates across recall periods for all age groups. This is true in particular for school-aged children between the ages of 5 and 13 years (Figures 7b and 7c). A sharp decline in both minor and severe rates across the first 3 months of recall intervals is found among preschool children. For children from 5 through 9 years of age, a decline in minor injury rates begins only after the 6th month of recall. Minor and severe rates for adolescents decline across recall intervals, although the decline of minor injuries appears to be stronger.

Discussion and Recommendations

The findings presented above suggest that varying recall periods used for calculating national estimates of annual injury rates can be expected to have profound effects on both the magnitude

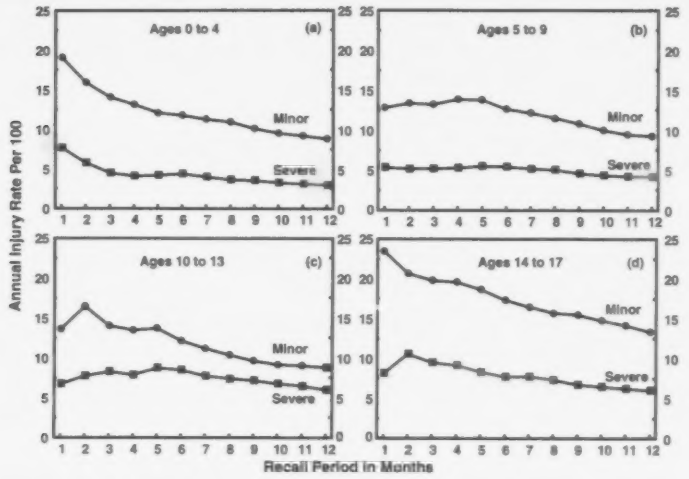

FIGURE 7—Age-specific estimated annual injury rates, by severity and recall period.

and composition of injury estimates. The findings also suggest that recall bias, in varying degrees, is present for all subpopulations, regardless of injury severity, although the effects of recall bias are significantly lower for severe injuries. It is probable that the decline in injury rates across recall periods observed in this study is a function of (1) loss of memory and (2) the "telescoping" tendency to report injury events as if they occurred in more recent calendar months than they actually did. The fall from 26.4 per 100 for a 2-week recall period to 24.4 per 100 for a 1-month recall period suggests that telescoping may be causing overestimation of injury rates by using such a small recall period as 2 weeks. The tendency to recall past events as if they occurred closer to today may cause some respondents to report an event occurring 15 or 16 days ago as if it occurred in the 14 days prior to interview. Reporting error of this type is magnified by a factor of 26 when calculating an annual rate based on a 2-week period. A similar telescoping error results for a 1-month recall period with half the magnitude of bias. Unfortunately, there is no way to test the telescoping hypothesis with the NHIS CHS data alone.

According to the results for all injuries, the incidence of medically attended injuries among American children can vary from a high of one injury in three children per year, based on a 2-week recall period, to a low of one injury in seven children per year, based on a 12-month recall period. By any public health standard, such differences are unacceptable when rates are used to determine priorities in allocating resources for preventive interventions. From an empirical research point of view, such differences imply that results cannot be compared across studies using different recall periods without a clear understanding of the factors affecting the differences in rates.

Sex and Age Differences

Many critical policy decisions are made on the basis of age-specific differences in injury rates. The American Academy of Pediatrics guidelines for well-child supervision,[16] for example, place more emphasis on injury prevention for preschool children than on prevention for older children and adolescents. A recent review of one series of federally funded research projects investigating the patterns and determinants of childhood injuries suggests that nearly 50% of the projects focus on preschool children, compared with only 7% devoted to adolescent injuries.[17] A reason for the emphasis on younger children is suggested from the findings shown in Figure 4. A report based on a 1-month recall period would conclude that children newborn through 4 years experience a relatively high injury rate, second only to the rates of adolescents aged 14 through 17 years. On the other hand, a report basing its findings on a 12-month recall period would conclude that children newborn through 4 years have lower injury rates than children of all other ages.

Severity of Injury

It is assumed that the reporting of severe injuries is less likely to be affected by increased recall periods than is the recall of minor injuries, and that different measures of injury severity will result in different patterns of injury recall, especially when the mother is the source of information. From analyses provided in this report, injuries with serious effects on daily life—for example, loss of school days, surgery, and hospitalization—are less susceptible to memory decay than minor injuries. Consequently, injury patterns emerging from short recall periods have a higher proportion of *minor* injuries than do injury patterns based on longer recall periods.

Recall Bias Issues Not Covered by This Study

The recall bias issues described in this report are applicable only to proxy information obtained from sampled children's parents. It is likely that similar declines in estimated annual injury rates might be found for rates based on responses obtained from the sampled children themselves. However, children, especially adolescents, may or may not recall injuries for reasons different from those of their parents. It is strongly recommended that a similar recall bias analysis be conducted on national data on adolescent injuries based on self-reports. A comparison of recall patterns from such an analysis with those presented above might provide further insight into the different recall forces that affect parents and children.

Implications for Analysis and Interpretation of National Survey Data on Childhood Injuries

The results of this study will help guide the analysis and interpretation of results using information from population-based surveys. In most cases, questions about injuries use one recall period (usually a 12-month period) as a basis for information. Findings based on such data may be influenced by recall bias and should be interpreted accordingly. To

account for recall effects, analyses should be repeated for minor and severe injuries. It is also recommended that researchers conduct sex-specific analyses by the four age categories presented in this paper: preschool children (0 through 4 years), elementary school aged children (5 through 9 years), middle school aged or pubescent children (10 through 13 years), and adolescents (14 through 17 years).*

Implications for the Design of Future Survey Questionnaires

National surveys are a critical source of information for monitoring and studying trends in injuries in childhood and adolescence. The need to include as many injuries as possible in such databases will result in the adoption of a 12-month rather than a 2-week or 1-month recall period. For this reason, it is strongly recommended that retrospective information gathered include the exact time (the date or at least the calendar month) when each reported injury took place. From this timing information an assessment of the magnitude and composition of recall bias can be made as a first step in analyzing the data. Such a procedure will provide more reliable and accurate information, which is essential for developing national intervention priorities. □

Characteristics of Adolescent Work Injuries Reported to the Minnesota Department of Labor and Industry

David L. Parker, MD, MPH, William R. Carl, MS, MPH, L. Ronald French, PhD, and Frank B. Martin, PhD

ABSTRACT

Objectives. The purpose of the study was to provide descriptive data and incidence data on adolescent work-related injuries and to determine whether such injuries are underreported to the Minnesota Department of Labor and Industry.

Methods. The study consisted of a 1-year survey of 534 adolescent work-related injuries reported to the Department of Labor and Industry and a cross-sectional survey of 3312 public high school students from throughout Minnesota. The high school survey used an abbreviated questionnaire with a subset of items from the Department of Labor and Industry survey.

Results. Ninety-six percent of the injuries were strains and sprains, cuts and lacerations, burns, bruises and contusions, and fractures. There were 11 hospitalizations; 4 were for burns that occurred during work in restaurants. Eighty workers (15%) reported permanent impairment as a result of their injuries. It was estimated that there were 2268 reportable injuries to working adolescents in Minnesota during the study year.

Conclusions. The most common serious injuries were injuries to the lower back and burns. The demographic characteristics of adolescents whose injuries were reported to the Department of Labor and Industry were similar to those of injured adolescent workers identified through the high school survey. The results suggest that there is substantial underreporting of adolescent work injuries. (*Am J Public Health.* 1994;84:606–611)

Introduction

National estimates of the rate of injury to adolescent workers range from 6.6 per 100 full-time female workers to 12.6 per 100 full-time males.[1] In a recent study from Massachusetts the injury rate for adolescents working part-time was estimated to be equivalent to 16 per 100 full-time workers.[2] Most of these injuries are lacerations, strains and sprains, and heat burns.[1] These data are supported by findings from Minnesota.[3]

Although it has been postulated that many adolescent work injuries may be severe, there are few descriptive data on the severity of adolescent occupational injuries.[4] It has also been suggested that such injuries may be underreported to workers' compensation systems in different states.[5]

In this paper we compare the occupational injury experience of adolescent workers identified through two methods: a survey of public high school students and interviews with adolescents identified via First Reports of Injury compiled by the Minnesota Department of Labor and Industry (DLI). We also evaluate the nature and severity of adolescent work injuries reported to the DLI during the period August 15, 1990, through August 14, 1991. Finally, we analyze the reporting of adolescent work injury events to the DLI, comparing these reports with data obtained from the survey of high school students.

Methods

Department of Labor and Industry Reports

Minnesota law requires that employers file a First Report of Injury for individuals who are fully or partially disabled from work for 3 or more days or who have permanent impairment as the result of a work-related injury or illness. Permanent impairment is defined by Minnesota statute for each condition. Data available from the DLI include personal identifiers for the injured worker, information on the source of the injury (e.g., hot oil, knife), the nature of the injury (e.g., cut, fracture), the event type (e.g., fall, explosion), the part of the body injured, and the date of injury.

For this study, we examined all reports for teenagers younger than 18 years at the time of injury who were injured during the period August 15, 1990, through August 14, 1991. Data from the reports were coded according to standards set by the American National Standards Institute (ANSI).[6] Employer and injury data from the reports were compared with data obtained by telephone interviews.

Parents of injured youths received a letter from the DLI explaining the nature of the Minnesota Department of Health study. A consent form asking for permission to obtain medical records and a postage-paid envelope were included with the letter. When telephone contact was made with the parents, information about family finances and

This paper was accepted June 29, 1993.

Editor's Note. See related editorial by Pless (p 537) in this issue.

health care insurance was obtained. Permission was also obtained to interview the injured youth. If contact was not made with both a parent and the injured worker, a time was arranged during which the interview could be completed. If there was no contact with any member of the family after six calls, a repeat mailing was sent requesting the family to contact the Department of Health.

Information was obtained from injured workers about their work history, the type of work in which they were engaged at the time of injury, the nature and severity of the injury, events surrounding the injury, and the possible impact of the injury on work, school, athletics, and other extracurricular activities. Injuries were coded according to ANSI guidelines as well as the 9th revision of the *International Classification of Diseases*.[7] Up to four types of injury (e.g., laceration, contusion) and four body parts (e.g., finger, elbow) were coded for each injury event. The source of injury was defined as the object, substance, exposure, or bodily motion that directly produced the injury (e.g., floor, hot oil). Event type (e.g., fall, explosion) was defined as the occurrence that led directly to the injury.

After receipt of a medical release form, the Department of Health obtained medical records from individual health care professionals. The nature and severity of the injury, the need for hospitalization, and permanent sequelae were validated by medical record review. Validation was done by an experienced nurse practitioner trained in medical record validation.

Survey of High School Students

In a second study, a sample of 3312 students enrolled in Minnesota public schools was selected through a two-stage stratified cluster sampling procedure.[8] For this sampling procedure, a list of all Minnesota public schools was compiled and grouped into strata according to the number of students in the school. Each stratum contained approximately 25% of the public high school population. Ten schools were contacted from each stratum to obtain administrative approval to conduct the survey. Within each school district, one teacher was chosen to coordinate the survey effort. That individual selected one classroom in each of the school's upper grades (10th, 11th, and 12th) to receive the survey. Data from St. Paul included a sample of 9th-grade students. Survey questions were identical to those used in telephone interviews of workers with injuries reported to the DLI. Again, event type and source of injury were coded according to the ANSI classification system. Analysis was confined to students younger than 18 years at the time they completed the survey.

[a]Data represent only students younger than 18 years at the time of the survey. Students in job training and work experience programs are excluded.
[b]Data represent persons younger than 18 years whose work-related injuries were reported to the Minnesota Department of Labor and Industry. Only injuries that occurred between August 15, 1990, and August 14, 1991, were considered in this study.
[c]Urban schools are those in which 13% or fewer students indicated that they lived on a farm.

Analysis

Data were analyzed with SPSS software (SPSS Inc, Chicago, Ill) for Unix operating on a Sun computer. Injuries were considered severe if they limited normal activity and/or resulted in missed work for more than 3 days or resulted in permanent impairment from a herniated lumbar disc, amputation, or other chronic problem such as vision loss, hearing loss, or sensory loss. The possible association of injury severity with type of industry, nature of injury, source of injury, and event type was assessed. Significant differences were assessed by means of a chi-square statistic for two-way contingency tables.[8]

For subjects in the high school survey, total hours worked (exposure) were computed from the date a student began working at his or her most recent job or August 1, 1990, whichever occurred later. Accumulation of work hours ended with the date of survey. A severe injury was defined as one causing the student to miss more than 3 days of normal activity or one that caused a permanent problem. This definition was based on reporting laws in Minnesota that require employers to file a First Report of Injury for individuals who are fully or partially disabled from work for more than 3 days or who have permanent impairment as the result of a work-related injury or illness. Confidence intervals for rate of injury, average hours worked per week, and percent of students working were computed by the jackknife method with data aggregated by classroom.[9]

Estimation of the degree of underreporting of injuries was based on grade- and sex-specific data from the high school survey. These data were used to estimate (1) the percentage of students younger than 18 years in the sample who were working, (2) the percentage who experienced work-related injuries, (3) the percentage of all injuries that were reportable according to Minnesota law, and (4) the total number of reportable injuries for public high school students in Minnesota during the 1990/91 school year.

Results

A total of 742 adolescent work injuries were reported to the DLI from August 15, 1990, through August 14,

Age at first job	14.6	14.4, 14.7	14.1	14.0, 14.3	15.1	13.2, 17.0	14.9	12.7, 17.1
Hours/week in August 1990	25.0	23.6, 26.4	30.1	27.8, 32.5	28.9	26.8, 30.9	32.2	30.5, 34.0
Hours/week in 1990/91 school year	15.3	14.2, 16.3	17.1	16.0, 18.3	20.4	19.1, 21.7	22.6	21.3, 23.8

[a]Data represent only students younger than 18 years at the time of the survey. Students in job training and work experience programs are excluded.
[b]Data represent persons younger than 18 years whose work-related injuries were reported to the Minnesota Department of Labor and Industry. Only injuries that occurred between August 15, 1990, and August 14, 1991, were considered in this study.

TABLE 3—Percentage of Adolescents Performing Specific Types of Work

		High School Survey[a]		First Report of Injury[b]	
Primary Industry	Type of Work	Females (n = 812)	Males (n = 866)	Females (n = 225)	Males (n = 309)
Agriculture	Farm laborer	5	20	1	1
	Yard keeper/landscaper	3	14	0	2
Construction	Laborer	1	8	0	0
Professional	Nurse's aide	5	<1	7	4
Restaurant	Dish buser	11	10	7	6
	Carhop	13	7	8	13
	Cashier	35	16	14	14
	Fast-food cook	9	8	14	12
	Short-order cook	7	11	7	11
	Dishwasher	12	12	11	13
	Waiter/waitress	19	1	5	4
Wholesale/retail	Janitor	9	15	45	43
	Sales clerk	12	5	2	2
	Stock clerk	5	8	15	16
	Bagger/carry-out person	3	8	15	16

Note. Numbers are percentages of column n's
[a]Data represent only students younger than 18 years at the time of the survey.
[b]Data represent persons younger than 18 years whose work-related injuries were reported to the Minnesota Department of Labor and Industry. Only injuries that occurred between August 15, 1990, and August 14, 1991, were considered in this study.
[c]Each participant indicated from one to three activities that best described the work done on the job; therefore percentages may total to more than 100.

1991. For 78 workers (10.5%), neither the worker nor a parent could be reached after repeated attempts by telephone and mail. Of the remaining 664 workers, participation was refused by 47 parents or guardians (7.1%). Contact with 83 parents (12.5%) resulted in a brief interview with the parent only. Therefore, complete survey information was provided by 534 of 664 study participants (80.4%). According to information from the First Reports of Injury, no significant differences in age, sex, nature of injury, or industry of employment were seen between the 208 nonparticipants or incomplete participants and those who completed the entire interview process. These 208 were excluded from further analysis.

Medical records were obtained from 17% of the participants. The only discrepancy between participant interviews and medical records concerned the presence of permanent impairment. The concordance between the reports of study subjects and medical records on permanent sequelae was 63%. Information was not available in the medical record to make a decision about permanent sequelae in 24% of the cases.

Tables 1, 2, and 3 compare the sociodemographic characteristics, work profiles, and job activities of the 534 subjects who had injuries reported to the DLI with those of subjects from the high school survey. Except for subjects from St. Paul, the two samples had similar age, race, and sex distributions for working adolescents. More jobs such as janitor, stock clerk, and bagger occurred in the job descriptions of the DLI sample. School survey respondents from St. Paul were different from all other school survey respondents and from the DLI sample in the following ways: (1) a higher percentage of students were from minority groups and (2) fewer students reported living on farms.

Table 4 shows the injuries most commonly reported to the DLI that resulted in altered activity such as missing school or missing work. In order of frequency of occurrence, these injuries were strains and sprains, cuts and lacerations, burns, bruises and contusions, and fractures. These five groups accounted for 96% of the injuries.

In addition to being the most frequent injury, sprains and strains were the most common cause of severe injury. Injuries to the low and mid back accounted for 73% (147) of all sprain and strain injuries. Most back injuries occurred in janitorial work (48%) and nursing work (21%).

The likelihood of sustaining a back injury was positively associated with the amount of weight individuals lifted at work ($\chi^2 = 17.1$, $P < .0001$). Of the 157 severe injuries, 61 were to the back ($\chi^2 = 14.3$, $P < .001$), and 13 workers reported injuries to the lumbar disc. Larger individuals tended to lift larger amounts of weight than smaller workers. Whether size was determined by body weight ($\chi^2 = 8.1$, $P < .005$) or body mass index[10] ($\chi^2 = 7.9$, $P < .005$), back injuries were more common in smaller workers than larger workers. For those

suffering from severe back injuries, there was a trend for smaller individuals to have more serious lifting injuries than their larger peers. No other injuries were associated with the size of the worker.

Lacerations, cuts, and abrasions were the second most common injuries and most frequently affected the hand (16%) and fingers (61%). Lacerations were often less severe than other injuries. No specific industry or job activity appeared to place workers at increased risk for these types of injury. Although few in number, those working as butchers tended to have severe lacerations.

Burns were the third most common injury. Although only 13% of all injuries were burns, burns contributed to 36% of hospitalizations. Fast-food and full-service restaurants contributed 28 (39%) and 26 (37%) burns, respectively. The most common sources of burn injuries in fast-food restaurants were cooking oils and grills and other cooking equipment. In full-service restaurants, the most common sources of burn injuries were cooking oils and hot water.

Sixty-seven individuals sustained bruises and contusions. These injuries tended to be less severe than others. The most commonly affected sites were the hand and fingers (25%), knee and arm (16% each), and back (15%). The most common event types were being struck by or against objects (37%) and falls (38%). These injuries were positively associated with two jobs: bagger and stock clerk.

Forty-seven individuals sustained fractures, and these injuries were often severe ($\chi^2 = 18.4$, $P < .001$). The most commonly affected site was the finger (43%), followed by the foot and toe (19%). Other significant sites included the skull, face, neck, and back. No specific industry appeared to place individuals at increased risk for fracture injuries.

Eighty workers (15%) indicated that they had permanent impairment as a result of their injuries (Table 5). There were no statistically significant associations between permanent impairments (e.g., amputations) and school days missed. However, the amount of school missed was associated with injury to the back and neck, but not to other body areas. Burns and strains and sprains were the injury types that most commonly resulted in missed school days.

Data from the high school survey were used to calculate the rate of injuries that resulted in adverse outcomes: 16 per 100 000 hours worked for all urban and rural students (95% confidence interval = 12, 19). Although it was not statistically significant, there was a trend for an inverse relationship between risk of injury and grade level. That is, fewer job injuries were observed at higher grade levels.

An estimated 2% of all working students had injuries that resulted in more than 3 days of limited activity and at least some missed work. There were 189 000 public school students in grades 9 through 12 in the 1990/91 school year in Minnesota,[11] and the results of the high school survey indicated that 60% of public high school students (113 400) held a regular job at some time during the study period. Therefore, our results suggest that 2268 reportable injuries occurred to adolescents during the study year ($0.60 \times 189\,000 \times 0.02 = 2268$).

TABLE 4—Nature and Consequences of Injuries to Adolescent Workers Most Commonly Reported to the Minnesota Department of Labor and Industry (DLI)

Result	Strains and Sprains (n = 201)	Cuts and Lacerations (n = 129)	Burns (n = 70)	Bruises and Contusions (n = 67)	Fractures (n = 47)	All Injuries (n = 534)
Limited activity days

Note. Numbers are percentages of column n's. The five types of injury shown here accounted for 514 (96%) of the 534 injuries for which DLI information was complete. Data for the remaining 20 injuries (not shown) were taken into account in computing the percentages shown for all injuries.
[a]Includes one person for whom injury severity data were incomplete.

TABLE 5—Characteristics of Permanent Impairments for Adolescents with Work Injuries Reported to the Minnesota Department of Labor and Industry

Characteristic	No. of Injuries in Each Category Possessing Characteristic					
	Strains and Sprains	Cuts and Lacerations	Burns	Fractures	Amputations	All Injuries[a]
Chronic pain	13	1	0	3	0	21
Scarring	0	11	31	2	1	45
Limited use of						
Finger(s) or hand(s)	1	6	0	5	3	15
Arm(s)	1	0	0	0	0	2
Leg(s)	1	0	0	1	0	2
Sensory loss	1	6	0	0	1	10

[a]A total of 80 workers reported some type of permanent impairment. The numbers in this column total to more than 80 because some workers reported multiple impairments.

Discussion

This study provided the opportunity to evaluate adolescent work injuries by two methods. The DLI study allowed for an evaluation of the nature and severity of adolescent work injuries, and the school survey provided information on the proportion of adolescents who work and the frequency of adolescent work-related injuries. The DLI study was constrained by probable underreporting and a small number of injuries. The school survey was limited by administrative constraints in obtaining a truly random sample of public high schools. Students from the larger population centers constituted 30% of the school survey population, compared with 41% of the 1990 Minnesota student population.

The primary source of data for the DLI is the First Report of Injury submitted by employers and insurance carriers to the state. In Minnesota, there has been no independent audit of the completeness of workers' compensation reporting by employers. Because the primary reason for reporting is missed work time, use of this measure alone may be misleading if workers return to work prematurely or in a limited capacity.[5,12,13]

In the school survey, disability was measured by the length of time the injury limited a worker's normal activities, the duration of missed work and/or school, and the presence of permanent sequelae. In the DLI study, disability was measured by the duration of missed work and/or school and the presence of permanent sequelae. Each of these methods portrayed a slightly different picture of injury-related disability. Although missed work was the most common limitation experienced by workers whose injuries were reported to the DLI, approximately 12% of the study subjects reported having missed no work.

This study suggests that two thirds of adolescent work injuries were not reported to the Minnesota DLI. This estimate is conservative for several reasons: (1) A large number of adolescent work injuries reported to the DLI did not result in missed work. (2) Agriculture-related work injuries constituted only 1% of all adolescent injuries reported to the DLI, and approximately 40% of male students in rural Minnesota were engaged in agricultural work according to the school survey. (3) There was a 3% high school dropout rate during the 1989/90 school year. Neither these individuals nor individuals who left school in previous years were included in estimates of the number of high school workers or the population upon which this estimate was based. The risk of injury to those who left school is unknown.

Sample size limited our ability to assess the effect of age and stature on injury occurrence and severity. When age was controlled, smaller workers did, however, experience back injuries more frequently and have more severe injuries than larger workers.

Although the epidemiology of low back pain in adolescents is not well understood, it is a matter of concern that approximately 9% of all acute back injuries resulted in herniated lumbar intervertebral discs. A recent prospective survey of 1246 students[14] indicated that 22% of adolescents experienced low back pain within the previous 12 months, and the risk of experiencing low back pain increased with age. This estimate is similar to the 26% reported in a study of secondary school students in Britain.[15] Data from the Minnesota high school survey suggest that 2% of all high school students may experience a work-related back injury each year. This estimate suggests that work contributes to, but is not a primary cause of, back pain in adolescents.

In past studies, burns constituted approximately 11.4% of work-related injuries to adolescents vs 1.8% of all occupational injuries.[3] According to data compiled by the New England Regional Burn Center, for burns requiring hospitalization, 25% of burns to boys and 19% of burns to girls aged 16 through 19 years were work-related. The rate for work-related burns was 143 per 100 000 for boys and 15 per 100 000 for girls.[16] No explanation was presented for the large discrepancy between boys and girls.

In general, work-related burns appear to be a substantial but largely neglected problem in the working population.[16] Existing studies suggest that Black men, food preparers, and younger workers are among those at high risk for work-related burns. Although scalding is the most common cause of industrial burns, flame and electrical burns are the most severe.[17] Grease burns constitute about 8% of all burn injuries in Utah and frequently result in admission to hospital burn units.[18] Deep-fat-fryer oils are maintained at approximately 350°F (177°C), and some filtering systems require as many as four steps of lifting and pouring hot oils.[18] The disposal of oils may require that large quantities of oil be carried in a bucket by hand. No protective equipment is used during either process. Hot oil accounted for 35% of all burn injuries in the DLI study.

Serious work-related injuries were identified in the course of this study. These included numerous cases of herniated intervertebral discs, burns, traumatic brain injuries, and amputations. These data suggest that adolescent work injuries may be a serious problem deserving increased attention. Similarities between the two study samples support underreporting of adolescent work injuries to the DLI. Currently, there is a lack of even the most basic descriptive information on adolescent and child employment in the United States.[4] Owing to the sporadic nature of adolescent work, information on adolescent work and occupational injuries should be obtained by population-based surveys. Estimates based on workers' compensation data leave doubts about the completeness of case ascertainment. □

American Congress of Rehabilitation Medicine to Hold Annual Meeting in June

The American Congress of Rehabilitation Medicine (ACRM) will hold its 71st annual meeting, "Benefits of Rehabilitation—Measure for Measure," June 10 through 12, 1994, at the Hyatt Regency Minneapolis in Minneapolis, Minnesota. The latest theories and techniques in outcome measurement will be featured. The meeting will be an opportunity to showcase what rehabilitation professionals do know about the benefits of rehabilitation and to suggest what still must be demonstrated about the cost-effectiveness of rehabilitation care. The conference is designed for members of ACRM and other healthcare professionals with the responsibilities of delivering high-quality rehabilitation services and achieving positive outcomes for patients.

The education program will feature a variety of presentation methods, including breakfast focus sessions with small-group participation, courses led by experts in specialized areas of study, symposia and scientifically-based panel presentations, workshops providing hands-on experience, and scientific paper and poster presentations. Content will cut across all rehabilitation professions, roles and practice settings.

For more information, contact the ACRM, 5700 Old Orchard Rd, First Floor, Skokie, IL 60077-1057; tel (708) 966-0095; fax (708) 966-9418.

Factors Associated with the Use of Violence among Urban Black Adolescents

Robert H. DuRant, PhD, Chris Cadenhead, BA, Robert A. Pendergrast, MD, MPH, Greg Slavens, BBA, and Charles W. Linder, MD

ABSTRACT

Objectives. The purpose of this study was to examine social and psychological factors associated with the use and nonuse of violence among Black adolescents living in a community with a high level of violent crime.

Methods. Adolescents (n = 225, 44% male) 11 to 19 years of age living in or around nine housing projects in an urban area were administered an anonymous questionnaire.

Results. Self-reported use of violence was associated with exposure to violence and personal victimization, hopelessness, depression, family conflict, previous corporal punishment, purpose in life, self-assessment of the probability of being alive at age 25, and age and was higher among males.

Conclusions. These data support the hypothesis that exposure to violence is associated with adolescents' self-reported use of violence. However, adolescents with a higher sense of purpose in life and less depression were better able to withstand the influence of exposure to violence in the home and in the community. (*Am J Public Health.* 1994;84:612–617)

Introduction

Violence among America's youth has emerged as a significant public health problem[1–7] for which no effective prevention method has been found,[2] and the problem disproportionately involves minority youth.[4] Homicide is the leading cause of death among young Black men 15 to 19 years of age and occurs at a rate nine times that for young White men of the same age.[8] The homicide rate for young Black women has also been found to be 3.5 times higher than that for young White women from the same age group.[3] The National Crime Survey Report estimated that, in 1989, 1.2 million youth 12 to 19 years of age were victims of single-offender crimes and 646 750 were victims of multiple-offender crimes, including robbery, simple assault, aggravated assault, and rape.[9,10] Adolescent violence is a multifaceted problem, and research on its causes is needed to provide requisite data for the development of prevention and intervention programs.

Violence is not a uniquely racial problem,[9–11] and its excess mortality by race is almost entirely accounted for by social factors associated with poverty and unemployment.[2,12–14] Within this social environment, cultural transmission theory proposes that crime and delinquency are learned in interaction with other people, largely within intimate primary groups such as families, peer groups, or gangs.[15] There is extensive evidence that many children and adolescents are continuously exposed to high levels of violence throughout their lives and that this socialization may have a significant effect on the increase in violent behavior observed over the last 40 years.[16] This includes witnessing violence on television and in movies, in the community, and in the home[2,17–21]; the proliferation of gun ownership by adolescents[22–24]; and being a victim of violence, severe corporal punishment, and early physical abuse.[25–40] However, not all adolescents who live in communities with high levels of poverty and unemployment and who are exposed to or are victims of violence engage in violent behavior. Many of these young people demonstrate unexpected resilience in the face of such social insults. Identification of resiliency factors will help in the development of effective prevention programs for urban adolescents who are exposed to social conditions that place them at risk of engaging in violent behavior. The purpose of this study was to examine the relationships between self-reported exposure to or victimization by violence and the use of violence among Black adolescents living in communities characterized by high levels of poverty, unemployment, and violence. Social and psychological factors associated with resiliency among these youth were also examined.

This paper was accepted November 10, 1993.

Methods

Subjects

The study was conducted on 225 Black adolescents living in or around nine US Department of Housing and Urban Development housing projects in Augusta, Ga. The subjects ranged in age from 11 to 19 years. A description of the subjects is provided in Tables 1 and 2.

Procedures

The study protocol was approved by the Human Assurance Committee of the Medical College of Georgia. Eight adolescents living in the targeted housing projects were identified by community health workers and enlisted to recruit subjects. The recruiters were asked to contact as many adolescents in their project area as was possible by delivering a parental and youth informed consent form along with information as to when and where the questionnaires were to be administered. The recruiters were paid $1 for each subject who completed a questionnaire. Nonresponse data for those potential subjects who were asked to participate but refused were not collected by the recruiters. To reduce the sampling bias, adolescents living in these housing projects who would not have had the opportunity to attend the scheduled survey sessions because they were participating in summer school (n = 23) or in a housing authority summer enrichment program (n = 40) were invited to participate. More than 90% of eligible subjects (n = 63) in these programs participated in the survey. These three groups of subjects, as well as the recruiters, did not differ on any demographic variable or in self-reported violent behavior. Questionnaires were administered in the housing project community centers, a local school during a summer enrichment program, and an area high school holding summer school. In addition, the questionnaire was administered to a small number of subjects in the conference room of Georgia's Children and Youth Project, which provides health care to children and adolescents living in Department of Housing and Urban Development housing projects. Written parental and subject informed consent was obtained, and the subject's name was not placed on the questionnaire.

To control for variations in reading ability, the questionnaire was read aloud by trained interviewers to groups of subjects ranging in size from 3 to 40; the instrument required between 45 and 60 minutes to administer, depending on the size of the group and the number of questions asked by the subjects. In no cases were subjects' parents present when the questionnaire was administered. Subjects were paid $5 for completing the questionnaire.

No answer or don't know	4	1.8	

Questionnaire

The questionnaire was constructed from several standardized measures described in the following paragraphs. These instruments were chosen because they have been used extensively among minority youths. In order to assess the stability of the subjects' responses over time, 12 subjects representing each of the survey administration sites were administered the same questionnaire 1 week later. These subjects were given $10 for the retest of the questionnaire. One-week test–retest reliability coefficients were computed on these subjects. For the total sample (n = 225), each constructed scale underwent item analysis and was tested for reliability (internal consistency) with Cronbach's alpha.

Adolescents' use of violence was measured with selected items from the Denver Youth Study Self-Reported Delinquency Questionnaire[41] and items

from the Centers for Disease Control and Prevention's Youth Risk Behavior Survey. Items from these two instruments were combined to create an eight-item scale that was tested for reliability. On the basis of item analysis, seven of the eight items were found to have high internal consistency. These included questions measuring the carrying and use of weapons, fighting and assaults, and involvement in gang fights (see Table 3). The use of violence scale, which ranged from zero to seven, had a Cronbach's alpha of .68 and a 1-week test–retest reliability coefficient of .86 (see Table 4).

Exposure to and victimization by violence in the community were assessed with questions from Richters and Martinez's Survey of Exposure to Community Violence.[33] This survey measures the frequency of exposure to or being a victim of 27 types of violence such as gang violence, selling drugs, burglary, police arrests, assaults, physical threats, sexual assaults, weapon carrying, firearm use, and intentional injuries such as stabbings, shootings, suicides, and murders. On the basis of item analyses, questions measuring exposure to violence had high internal consistency with questions assessing victimization by crime and violence. When separate scales were constructed for being exposed to violence and victimization, the alphas were smaller than for the full scale of 27 items. This 27-item self-report scale, which ranged from 0 (low exposure or victimization) to 116 (high exposure to violence), had a Cronbach's alpha of .85 and a test–retest reliability coefficient of .90.

Exposure to domestic conflict and violence was assessed through a modified version of the Conflict Tactics Scale.[42] This 20-item scale has good concurrent validity when correlated with other measures of parental psychosocial distress.[43] In the present study, 1 item was found to have poor internal consistency with the other 19 items and was discarded. The revised scale ranged from 19 (indicating low domestic conflict) to 71 (representing high conflict). The scale had a Cronbach's alpha of .86 and a test–retest reliability of .97.

The Home Environment Interview, Version II, was used to assess disciplinary activity in the home.[32] This 6-item scale was modified slightly to measure current rather than retrospective patterns of corporal punishment. The scale ranged from 0 to 6 (high disciplinary activity) and had a Cronbach's alpha of .58. However, the test–retest reliability was only .24.

The Children's Depression Inventory was used to measure a variety of symptoms of depression.[44] This 27-item self-report measure has been found to have good reliability and to correlate well with other similar psychological scales. The instrument has a potential range of 0 to 54, with 54 suggesting the maximum level of depression. In this sample, the scale ranged from 0 to 31 and had a Cronbach's alpha of .82 and a test–retest reliability of .84.

The Hopelessness Scale for Children was used to measure subjects' negative expectations about the future.[45] This 16-item scale, which ranges from 0 (indicating low hopelessness) to 12 (indicating a high level of hopelessness), had a Cronbach's alpha of .64 and a test–retest reliability coefficient of .61.

The Purpose in Life test was designed to measure the level of perceived meaning in one's life.[46,47] It has been found to measure a construct distinctly different from locus of control.[48] Each of the 14 items was scored on a 7-point scale so that the minimum ("worst") score was 14 and the maximum was 98. The subjects' scores ranged from 35 to 98, and the scale had a Cronbach's alpha of .86 and a test–retest reliability coefficient of .61.

A 5-point scale was created to determine subjects' certainty of being alive at age 25. The choices ranged from "I am absolutely sure that I will live to be 25 years of age" (scored as 1) to "I am absolutely sure that I won't live to be 25 years of age" (scored as 5). This scale had a test–retest reliability of 1.0.

Subjects' religious activity was assessed with two items. First, the subject was asked whether he or she was a member of any church or religious organization. Second, a 5-point scale was used to determine frequency of church attendance or religious activity. Test–retest reliability was .82 for the former and .60 for the latter.

Four questions were asked to assess family structure. These questions involved the total number of people in the home, whether the subject lived with a parent or adult relative, the subject's birth order, and the identification of the head of the subject's household. All of the questions had a test–retest reliability of .89 or better.

Future aspirations were assessed with two questions. Subjects were asked, "If you could do whatever you wanted, what type of job or profession do you want to have when you grow up?" The answers were scored on a 7-point ordinal scale based on the educational level needed to achieve the professional goal (with 1 being the highest educational level). At a separate point in the questionnaire, the subjects were asked what kind of job they saw themselves doing when they were 25 years of age. This question was scored in the same manner as the preceding question. The test–retest correlation for these questions was .91.

Parents' socioeconomic status was based on the expected educational level needed to qualify the parents for their current job or profession. This was scored on a 7-point ordinal scale, with 1 indicating the highest socioeconomic status level (professional job requiring a doctoral degree), 6 indicating employment not requiring a high school education, and 7 indicating unemployed status.

Statistical Analysis

Interval and ordinal data are summarized as the mean ± standard deviation. Bivariate analyses were conducted with Pearson product moment correlation coefficients, analysis of variance, and chi-square tests. Variables found to be significantly ($P \leq .05$) associated with adolescents' use of violence were analyzed with stepwise multiple regression. Because of missing values on some variables, the regression analysis was conducted on the subjects with complete data (n = 209).

Results

Eighty-four percent of the adolescents reported engaging in at least one form of violent behavior. The percentages of male and female subjects engaging in each type of violence are reported in Table 3. The mean response on the violence scale was 2.1 ± 1.7, with a median score of 2.0 and a skewness of 0.94 ± 0.16. The exposure to violence and victimization scale was normally distributed, ranging from 0 (low) to 116 (high). The mean response of 44.2 ± 22.6 suggests that the subjects in this study had been frequently exposed to and been victims of violence (Table 4).

Male subjects (2.1 ± 1.8) reported engaging in significantly ($P \leq .01$) more violent behavior than female subjects (1.8 ± 1.6). Self-reported use of violence was positively correlated with previous exposure to violence and victimization;

levels of hopelessness, depression, and family conflict; previous corporal punishment; and age. Use of violence was negatively correlated with the purpose in life scale and expectancy of being alive at age 25 (Table 5). Use of violence was not significantly correlated with resiliency factors such as family structure, socioeconomic status, religious behavior, or any other demographic variable. However, a factor indirectly associated with resiliency, higher purpose in life score, was correlated with greater frequency of attendance at religious services ($r = .20$, $P \leq .004$) and a higher socioeconomic status of the head of household ($r = -0.20$, $P \leq .004$). Also, subjects who lived in households in which the head of household was employed had a significantly higher purpose in life score ($P \leq .003$), had fewer feelings of hopelessness ($P \leq .017$), and were more likely to believe they would be alive at age 25 ($P \leq .016$) than adolescents from homes with unemployed heads of households.

When each of the variables found to be significantly associated with use of violence was analyzed with stepwise multiple regression, previous exposure to violence and victimization was the strongest predictor of use of violence, explaining 26.6% of its variation (Table 6). The depression scale was entered as the second variable in the regression model, explaining an additional 3.8% of the variation in use of violence. Gender explained an additional 1.6% of variation in use of violence as the last variable entered into the model. The interaction effects between gender and the other independent variables were not significant. These three variables accounted for 31.1% of the variation in the adolescents' use of violent behavior. Since the other variables significantly correlated with use of violence were also correlated with both exposure to violence and depression, they did not account for any additional variation in the regression model (Table 5). For example, depression was negatively correlated with purpose in life and positively correlated with corporal punishment, family conflict, and hopelessness (Table 5). Exposure to violence and victimization was positively correlated with age, family conflict, depression, and hopelessness and negatively correlated with purpose in life. These data suggest that factors associated with resiliency are not totally independent of the strongest predictor of adolescents' use of violence: their exposure to violence in the past.

TABLE 3—Items Included in the Use of Violence Scale

	Males		Females	
	No.	%	No.	%
Attacked someone they lived with out of anger	44	44.4	66	52.4
Involved in a physical fight in the last 12 months	64	64.6	70	55.5
In the previous 12 months, received an injury during a physical fight requiring medical care	12	12.1	9	7.1
Been involved in a gang fight	25	25.3	15	11.9
Carried a weapon such as a gun, knife, or club in the last 30 days	35	35.4	20	15.8
Ever carried a hidden weapon	41	41.4	31	24.6
Attacked someone with a weapon with the idea of seriously hurting or killing	19	19.2	17	13.5

TABLE 4—Means, Standard Deviations, and Reliability Coefficients for Social and Psychological Scales

	Mean	SD	Test–Retest Reliability	Cronbach's α
Desired socioeconomic status	2.9	1.6	.91	. . .
Anticipated socioeconomic status at age 25	3.5	1.9	.91	. . .
Church attendance	3.5	1.5	.60	. . .
Corporal punishment	0.9	1.3	.24	.58
Conflict Tactics Scale (family conflict)	34.9	9.9	.97	.84
Exposure to and victim of violence	44.2	22.6	.90	.85
Children's Depression Inventory	7.8	6.0	.84	.82
Hopelessness Scale for Children	2.4	2.3	.61	.64
Purpose in Life test	81.2	12.9	.61	.86
Alive at age 25	3.8	0.9	1.00	. . .
Use of violence	2.1	1.7	.86	.68

Discussion

Koop and Lundberg have stated that the solutions to violence are very complex and that research on the causes, prevention, and cures of violence is needed.[1] In this study, we addressed factors associated with Black adolescents' self-reported use and nonuse of violence. As expected, self-reported use of violence by these Black adolescents was significantly correlated with three indicators of previous exposure to violence: self-reported exposure to violence and victimization in the community, degree of family conflict, and severity of corporal punishment and discipline. Because these data were collected in a cross-sectional survey, we cannot imply causation between multiple exposures to violence and adolescents' reported use of violence. These relationships may be covariational in nature, with viewing violence in the community, personally experiencing violence and crime, witnessing violence and conflict among family members in the home, being a victim of severe corporal punishment, and actually using violence dynamically interacting with one another as these events co-occur. These data support the cultural transmission theory that has proposed that adolescents' use of violence is learned within intimate primary groups such as families, peer groups, and other sources for modeling such as gangs.[15] These data also support previous theoretical and empirical work suggesting that experiencing or being a victim of violence will increase the risk that an adolescent will, in turn, use violence against others.[16-21,25-33]

TABLE 5—Pearson Correlation Coefficients (*P* Values) between Black Adolescents' Use of Violence and Social and Psychological Scales

	Exposure to Violence	Age	Alive at Age 25	Purpose in Life	Corporal Punishment	Family Conflict	Depression	Hopelessness
Age	.22 (.001)	...	...	...	...	...	...	...
Alive at age 25	−.11 (NS)	.02 (NS)	...	...	...	...	...	...
Purpose in life	−.18 (.009)	−.04 (NS)	15 (.031)	...	...	...	...	...

Use of violence	.50 (.0001)	.17 (.01)	−.18 (.007)	−.26 (.0001)	.20 (.004)	.27 (.0001)	.32 (.0001)	.32 (.0001)

Note. NS = not significant.

TABLE 6—Multiple Regression Analysis of Black Adolescents' Use of Violence

	β	R^2 Change	*F*	*P*	*r*
Exposure to and victim of violence	.034	.266	74.99	.0001	.52
Depression	.062	.038	45.12	.0001	.32
Gender	−.443	.016	32.22	.0001	−.15
Constant	.822	...	...	...	...

Multiple R = .566; R^2 = .320; Adjusted R^2 = .311.

Although the depression scale was significantly correlated with the level of violent behavior, we cannot assume that depressed adolescents are more likely to commit violent acts. Because these data were collected by means of a cross-sectional survey, it is also probable that exposure to high levels of violence and involvement in violent activity could result in higher levels of depression among youth. However, these data indicate a definite association between depression and self-reported use of violence independent of the influence of previous exposures to violence.

Although these adolescents were living in a community characterized by high levels of poverty, unemployment, and criminal activity, 15.6% reported that they had never used any form of violence, and an additional 31% reported only one form or type (not event) of previous violent activity. Several variables were found to be associated with resiliency that enabled adolescents to resist engaging in higher levels of violence despite the presence of multiple risk factors. In support of resiliency theory,[34-39] adolescents who reported lower levels of hopelessness, had higher scores on the purpose in life scale, and believed there was a higher likelihood that they would be alive at age 25 were less likely to report engaging in violent behavior. Despite living in an environment that would be expected to facilitate feelings of hopelessness, little chance for successfully changing their life situations, and a chance that they may not live to be adults, many of these adolescents felt the opposite and correspondingly did not engage in violent behaviors. On the basis of research and theoretical work by Jessor,[36] Garmezy,[37] and Werner,[35-39] it would be expected that these relationships would be influenced by family structure, parental socioeconomic status, religious behavior, and parental employment status. None of these variables were associated with the use of violence by adolescents. This may be partly due to the small variation among categories for the family structure, parental socioeconomic status, and parental employment status variables. However, in support of resiliency theory, adolescents who attended religious services more often and whose head of household had a higher socioeconomic status were more likely to have higher purpose in life scores, which, in turn, were associated with less violent behavior. Also, living in a home with an employed head of household was associated with higher purpose in life scores, fewer feelings of hopelessness, and a higher likelihood of believing one would be alive at age 25.

To apply these findings to prevention programs, comprehensive and multifaceted approaches are needed.[4] A lesson that has been learned from the acquired immunodeficiency syndrome epidemic is that cognitive approaches to prevention, such as informing the public about a disease and how to safeguard against infection, do not exert much influence on health-impairing habits among adolescents.[49] The most effective health education programs aimed at preventing and/or changing adolescents' health-impairing behaviors have used a social cognitive approach based on social learning theory.[49,50] This approach assumes that health-impairing behavior is socially learned, purposive, and functional and is the result of the interplay of social-environmental and personal factors. For adolescents to achieve self-directed behavior change, they need to be provided not only with the reasons to alter high-risk behavior but with the means, resources, and social supports to do so. We propose that skill-building violence prevention programs centered on conflict resolution and violence avoidance and aimed at younger adolescents be developed and evaluated and that these programs include strong normative components. However, prevention programs will have a limited impact on adolescent violent behavior if they are not accompanied by institution- and community-level changes in many of the risk factors for engaging in violent behavior (i.e., high levels of violence in the home, community, media, etc.).

For many adolescents coming of age in the 1990s, violence is a daily reality. They experience it in their homes and communities and witness the irresponsible portrayal of violence on prime time television and in movies. Among minority youth living in lower socioeconomic urban areas, the hopelessness of social immobility and a lack of modeling of nonviolent conflict resolution skills in their homes and communities provide scenarios in which there are neither incentives nor skills to avoid the use of violence. At the very least, solving the problem will require both national and personal commitments in initiating prevention programs during childhood and early adolescence. □

Aggression and Fighting Behavior among African-American Adolescents: Individual and Family Factors

Niki U. Cotten, MPH, Jacqueline Resnick, BA, Dorothy C. Browne, DrPH, Sandra L. Martin, PhD, Donna R. McCarraher, MPH, and Joan Woods, MPH

ABSTRACT

Objectives. This study examined the extent to which individual and family factors are associated with aggression and fighting behavior among African-American middle school adolescents.

Methods. Four hundred thirty-six African-American boys and girls from two middle schools in a predominantly low-income North Carolina school system were surveyed and their school records examined. Information was collected concerning students' aggression levels, school fighting behavior, school suspensions for fighting, attitudes toward violence, perceptions of their families' attitudes toward violence, weapon-carrying behavior, and sociodemographics. Multivariate analyses were employed to predict the students' aggression levels, fighting behavior, and school suspensions.

Results. Factors related to the individual adolescents, such as gender, age, weapon-carrying behavior, and attitudes toward violence, were associated with students' reports of aggression and fighting behavior. Factors related to family and school were associated with school suspension for fighting.

Conclusions. This study suggests that violence prevention programs set in our elementary and middle schools may reduce aggression and fighting among our youth. School teachers and public health practitioners are encouraged to work together in understanding and preventing adolescent violence. (*Am J Public Health.* 1994;84:618–622)

Introduction

In the last decade, rates of violence-related child and adolescent fatalities have increased in the United States. Homicide, the third leading cause of death in adolescents 10 to 19 years of age,[1] accounted for 42% of the deaths among young African-American males during that period.[2] The homicide rate for African-American adolescents is six times that for White adolescents.[3]

Physical fighting is an antecedent behavior for many nonfatal and fatal intentional injuries.[2] Unfortunately, fighting appears to be common among adolescents. A recent survey found that 42% of adolescents reported fighting within the past year, and 26% had carried a weapon during the preceding month.[2]

Much of what is known about violence among African-American youth has been obtained from examining differences between this group and their White counterparts.[4,5] Few studies have examined intragroup differences in aggression and fighting in African-American populations.[6] Therefore, the question addressed in this paper is the extent to which individual characteristics of the adolescent (including gender, age, attitude toward violence, and weapon-carrying behavior) and family factors (including poverty status and students' perceptions of their families' views toward violence) predict aggression and fighting behavior among African-American adolescents.

Methods

Study Setting and Sample

Adolescents attending two middle schools in predominantly low-income African-American neighborhoods in a small North Carolina city were studied. Although only approximately half of the city population is African-American,[7] more than 90% of the children enrolled in the city school system are African-American.

A total of 744 students attended the two schools and therefore were eligible for the study. Ninety-seven percent of these students were African-American (53% male and 47% female). Four hundred forty-seven of these African-American students (60%) received parental consent for their participation in the study, were present in school on the day of the study assessment, and filled out the study questionnaires. Fifty-one percent of these 447 students were male, and 49% were female. Complete information on selected study variables was available for 436 students, of whom 222 (51%) were male and 214 (49%) were female. Therefore, this paper will focus on these 436 students.

Assessment

Student questionnaires. Self-administered questionnaires were given to the students during school, before the initiation of a violence prevention curriculum. Care was taken to establish rapport with

the students prior to administration of the questionnaires to maximize the probability of honest responses to sensitive questions. The questionnaires were administered by African-American college students who had been well trained in the administration procedures. Students were assured that their responses would be confidential and that neither teachers nor parents would see their answers. The questionnaire gathered information concerning characteristics of the students (i.e., aggressiveness, fighting behavior, attitudes toward violence, weapon-carrying behavior, gender, and age) and characteristics of the students' families (i.e., students' perceptions of their families' views toward violence).

The questionnaire assessed the students' aggressiveness, using an aggression scale developed on the basis of previous reliable and valid instrumentation.[8–10] The aggression scale listed 12 aggressive behaviors (e.g., threatening peers, destroying property) to which students responded by indicating whether each was never, sometimes, or often true of them. Item responses were summed to create an aggression score, with higher scores indicating more severe aggression (the lowest possible score was 0 and the highest possible score was 24). Internal consistency, as assessed by Cronbach's alpha, was .75, and test–retest reliability over a 3-month period was .60.

The questionnaire also contained a question adapted from the Youth Health Risk Behavior Survey[11] to ask about the students' participation in fights at school. Specifically, students were asked, "While you were at school, has anyone ever attacked or fought with you?"

The students' attitudes toward interpersonal peer violence were assessed with a scale adapted from one developed by the Education and Development Center Inc of Massachusetts. This scale listed 15 statements that expressed either a nonviolent or a violent orientation. Students responded to each item on a 4-point scale, with 1 indicating "disagree a lot" and 4 indicating "agree a lot." Endorsed responses were summed to create a student attitude scale score, with low scores indicating a nonviolent orientation (the lowest possible score being 15) and high scores indicating a violent orientation (the highest possible score being 60). Internal consistency, as assessed by Cronbach's alpha, was .73, and test–retest reliability over a 3-month period was .59.

TABLE 1—Description of the Students

	Female (n = 214)	Male (n = 222)	Total (n = 436)

No	180 (84)	173 (78)	353 (81)
Age, y, mean (SD)	12.5 (1.0)	12.5 (1.0)	12.5 (1.0)
Aggression score, mean (SD)	6.1 (3.5)	6.7 (4.2)	6.4 (3.9)
Student attitude toward violence score, mean (SD)	29.9 (6.5)	32.6 (7.7)	31.3 (7.2)
Perception of family attitude toward violence score, mean (SD)	12.0 (3.4)	12.3 (3.2)	12.2 (5.3)

Student weapon-carrying behavior was assessed with an item from the Youth Health Risk Behavior Survey. Students were asked whether they had ever brought a weapon (e.g., gun, knife, club) to school to protect themselves.

The students' perceptions of their families' views toward violence were assessed on a five-item instrument. Students responded to each item on a 4-point scale, with 1 representing "disagree a lot" and 4 representing "agree a lot." Endorsed responses to items were summed, with low scores indicating that the students believed that the family disapproved of interpersonal student violence (the lowest possible score being 5) and high scores indicating that the students believed that the family condoned interpersonal student violence (the highest possible score being 20). Internal consistency, as assessed by Cronbach's alpha, was .55, and test–retest reliability over a 3-month period was .54.

School record reviews. School records were searched to determine whether the students had been suspended from school for physical fighting, including hitting, biting, and kicking, within the past year.

Families of students were classified as living in poverty if school records showed that students were enrolled in the school free lunch program, indicating that a family of four must have had a monthly income of less than $1452.

Analysis

Multiple linear regression procedures[12] were used to model the students' scores on the aggression scale as a function of school, gender, age, student attitude toward violence scores, student weapon-carrying behavior, students' perceptions of their families' attitudes toward violence scores, and poverty. Regression coefficients and 95% confidence intervals (CIs) were use to measure effect sizes for the predictor variables.

Logistic regression procedures[13] were used to model the students' reports of their school fighting behavior as a function of the predictor variables used in the previously described multiple linear regression model. Odds ratios (ORs) and corresponding 95% confidence intervals were computed. The

TABLE 2—Results of Linear Regression Analysis of Student Aggression Scale Scores

	Regression Coefficient	95% CI
School	−0.27	−0.92, 0.39
Gender	−0.01	−0.67, 0.64
Age	0.50*	0.18, 0.81
Student attitude	0.19*	0.14, 0.24
Weapon carrying	1.10*	0.25, 1.95
Perception of family attitude toward violence	0.07	−0.04, 0.18
Poverty	0.44	−0.21, 1.09

Note. The following variable coding scheme was used in the multiple linear regression model of student report of aggression: aggression (score on aggression scale), school (0 = school A, 1 = school B), gender (0 = male, 1 = female), age (in years), student attitude (score on student attitude toward violence scale), weapon carrying (0 = no, 1 = yes), perception of family attitude toward violence (score on students' perceptions of their families' attitudes toward violence scale), and poverty (0 = no, 1 = yes). CI = confidence interval.
*$P < .05$.

school suspension records for fighting were modeled in a similar manner.

Results

Table 1 presents the characteristics of the sample stratified by gender. Boys constituted 51% of the students. Forty-two percent of the students were from school A, while the remainder were from school B. Forty percent of the students were in sixth grade, 28% were in seventh, and 32% were in eighth. The students ranged in age from 11 to 15 years (mean = 12.5 years). Fifty-one percent of the students' families lived in poverty.

One hundred sixty students (37%) reported that they had been involved in a physical fight at school (26% of the girls, 47% of the boys), and school records showed that 77 (18%) had been suspended from school for fighting (14% of the girls, 21% of the boys). Eighty-three students (19%) reported that they had carried a weapon to school (16% of the girls, 22% of the boys). Overall aggression scores of the students ranged from 0 to 20 (mean 6.4, SD = 3.9), with the mean male scores being higher than the mean female scores. Scores on the student attitude toward violence scale ranged from 15 to 55 (mean = 31.3, SD = 7.2), with the mean male score being higher than the mean female score. The scores on the scale measuring students' perceptions of their families' attitudes toward violence ranged from 5 to 20 (mean = 12.2, SD = 3.3).

Significant positive correlations were found between the students' reports of aggression and (1) their attitudes toward violence ($r = .42$, $P = .0001$) and (2) their perceptions of their families' attitudes toward violence ($r = .22$, $P = .0001$). Students' attitude scores were significantly correlated with their perceptions of their families' attitude scores ($r = .39$, $P = .0001$).

Regression diagnostic procedures detected no collinearity problems among the predictor variables used in the linear regression analysis (tolerance estimates ranged from .79 to .98). The results of the linear regression procedures, presented in Table 2, show that three of the variables focusing on the individual adolescents were significant predictors of aggression. Age was significantly related to aggression; older students were more aggressive than younger students. Student attitude toward violence was also significant; students with violent attitudes reported more aggressive behavior. Finally, students who carried weapons to school scored significantly higher on the aggression scale than those who did not carry weapons to school. The family-related factors and the school factor were not significant predictors of student aggression.

Table 3 shows that when the students' reports of fighting in school were modeled by means of logistic regression procedures, three of the individual factors were significant predictors. Gender was predictive of fighting in school, with girls being less likely to fight than boys (OR = 0.44, 95% CI = 0.29, 0.68). Age was also predictive of student fighting, with older students reporting more fighting than younger students (OR = 1.28, 95% CI = 1.04, 1.57). Student attitude toward violence was predictive of student fighting, with students who had more violent attitudes being more likely to report fighting (OR = 1.06, 95% CI = 1.03, 1.09). The family-related factors and the school factor were not significant predictors of student fighting.

The findings of the logistic model of school records of suspension for fighting, presented in Table 3, show that individual, school, and family factors were all associated with school suspension. Age was related to school suspension; older students were more likely to have been suspended from school for fighting than were younger students (OR = 1.54, 95% CI = 1.19, 1.99). School was significantly related to suspension for fighting, with the students in school B being less likely to be suspended than the students in school A (OR = 0.42, 95% CI = 0.25, 0.70). The family variable of poverty showed a borderline relationship to school suspension, with students of impoverished families being more likely to receive suspensions for fighting in school than students whose families were not impoverished (OR = 1.69, 95% CI = 0.99, 2.85).

Discussion

This study found that individual characteristics of the students, including age, gender, weapon-carrying behavior, and attitude toward violence, were predictive of their reports of aggressive behavior and fighting at school. The findings that age (being an older adolescent) and gender (being male) were associated with student aggression and fighting are consistent with the staggering rates of intentional injury and homicide among African-American adolescent boys.[3] Weapon-carrying behavior was also predictive of student aggression, suggesting that students may gain confidence and security from carrying a weapon and thus may perceive fewer risks to themselves in aggressive situations. Although student attitude toward violence was positively associated with aggression and fighting, students, on average, did not view violent behavior as the most appropriate response to conflict.

These findings suggest that violence prevention programs set in elementary and middle schools may be useful in the prevention of aggression and fighting among youth. Such programs should encourage nonviolent attitudes and teach nonaggressive conflict resolution strategies to give children the tools they need to reduce aggressive behavior. In addition, the findings stress the importance of ensuring that weapons are kept out of classrooms.

Neither family factors nor the school that the students attended were related to student reports of aggression and

fighting. However, a family factor, namely poverty, and school were associated with students having a school suspension record for fighting. Therefore, the question arises as to why students' reports of aggression and fighting were associated with characteristics of the students, while school suspension records for fighting were primarily related to school and family factors.

Discussions with school officials indicated that the discipline policies of the two schools varied greatly, with school A being more likely to use suspension than school B. Therefore, although the students at the two schools did not evidence differential levels of aggressive behavior or fighting at school, differences in school discipline policies resulted in greater proportions of students at one school being suspended for fighting.

The association between poverty and school suspension may be a statistical artifact since the relationship between the two factors is not a strong one. However, if we assume, for the sake of discussion, that this is not the case, other possible explanations arise. One explanation may be that adolescents from impoverished families were more frequently suspended for fighting because, although they fought as often as other adolescents, they were involved in more severe fights that alerted school officials. Post hoc analyses suggested that this was not the case, since 6% of impoverished students who fought reported receiving medical treatment for resultant injuries, as did 6% of nonimpoverished students. An alternative explanation may be that the poorer students were less likely than other students to report aggressive behavior and fighting, thus explaining the discrepancy between self-reported fighting and suspensions for fighting. We do not believe that this is a strong explanation given the great care taken to establish rapport with all students and to assure them of the confidentiality of their answers. Finally, school officials may have been more likely to suspend students from impoverished families than to suspend other students. Future research aimed at providing a better understanding of this finding is encouraged.

Our findings must be viewed with caution given the study limitations. Most of the data were derived from students' self-reports and, therefore, are liable to all of the self-report biases. In addition, it must be stressed that the students' perceptions of their families' attitudes toward violence may not reflect the views the families actually hold. Furthermore, we may not have accurately detected all of the students who were living in impoverished families because of our reliance on enrollment in the free school lunch program as the definition of poverty. Given the social stigma associated with participation in the free lunch program, students eligible for the program may not have enrolled. Therefore, while 51% of the students in this sample were classified as poor because of their free lunch status, the difference in the family financial status between the students whom we classified as impoverished and those we classified as nonimpoverished may not be great. Finally, it should be kept in mind that the analysis strategy that we chose to use (namely, forcing all of the predictor variables simultaneously into the models of the study outcomes) is just one of many approaches that could have been taken. Therefore, different analysis strategies may have led to somewhat different findings.

In conclusion, this study revealed fairly high rates of fighting behavior among African-American middle school students. School teachers and public health practitioners are encouraged to work together to address both the immediate and more subtle factors associated with adolescent violence in order to stem the escalating acts of aggression seen in our schools today. □

TABLE 3—Results of Logistic Regression Analyses of Student Report of Fighting at School and School Suspension Records for Fighting

	Student Report of School Fighting Model		School Suspension for Fighting Model	
	OR	95% CI	OR	95% CI
School	0.76	0.50, 1.15	0.42*	0.25, 0.70
Gender	0.44*	0.29, 0.68	0.69	0.40, 1.18
Age	1.28*	1.04, 1.57	1.54*	1.19, 1.99
Student attitude	1.06*	1.03, 1.09	1.03	0.99, 1.07
Weapon carrying	1.55	0.92, 2.62	1.16	0.61, 2.19
Perception of family attitude toward violence	0.94	0.88, 1.01	0.93	0.85, 1.01
Poverty	0.76	0.50, 1.15	1.69**	0.99, 2.85

Note. The following variable coding scheme was used in the logistic regression model of student report of fighting at school: school fighting (0 = no, 1 = yes), school (0 = school A, 1 = school B), gender (0 = male, 1 = female), age (age in years), student attitude (score on student attitude toward violence scale), weapon carrying (0 = no, 1 = yes), perception of family attitude toward violence (score on students' perception of their families' attitudes toward violence scale), and poverty (0 = no, 1 = yes). The same variable coding was used in the logistic regression model of school suspension record for fighting; however, the outcome of school suspension was coded as 0 = no, 1 = yes. OR = odds ratio; CI = confidence interval.

Traumatic Child Death and Documented Maltreatment History, Los Angeles

Susan B. Sorenson, PhD, and Julie G. Peterson, BA

ABSTRACT

Objectives. Child abuse is a presumed but largely untested risk factor for child homicide. This research investigated the social and child protective service history of child homicide victims.

Methods. A pairwise matched case–control design was used to assess documented child maltreatment as a risk factor for homicide vs unintentional injury death. Homicide victims aged 0 to 14 years were identified through Los Angeles Police Department case summaries. Control subjects (children who died of an unintentional injury) were matched to case subjects (children who died from homicide) by age, sex, race/ethnicity, and date of death. Case and control subjects were linked with county service records to determine any known history of maltreatment.

Results. A total of 220 children were homicide victims during 1978 through 1987 in the city of Los Angeles. Only one in six children who died (of homicide *or* unintentional injury) or his/her family was known to county social *or* child protective services prior to the death. Recorded history of child protective services was associated with homicide victimization (adjusted odds ratio = 3.40, 95% confidence interval = 1.25, 9.27).

Conclusions. Current service systems need assistance in identifying and protecting children at high risk of homicide. (*Am J Public Health.* 1994;84:623–627)

Introduction

Homicide is the fourth leading cause of death among 1- to 14-year-olds.[1] As Christoffel[2] reported a decade ago, it is the only leading cause of death among children that has increased in rank in the past 30 years,[3] with the exception of human immunodeficiency virus, which appeared recently in child death rankings. Although children make up a small portion of the nation's homicide victims, the years of potential life lost are significant.

Product approaches to the understanding and prevention of intentional injury (e.g., control of firearms)[4–6] are able to address a certain portion of homicides. Previous research indicates, however, that product-oriented countermeasures affect a relatively small portion of the homicides of children because few children, especially those at the youngest ages, are killed with a firearm.[7–15]

A common underlying assumption in prevention programs and in research on child maltreatment is that violence toward children is a continuum ranging from physical punishment through child abuse to homicide.[16–18] The focus of this investigation is whether a history of maltreatment is a risk factor specific to homicide or to child injury death in general.

The present study tested three research questions: (1) What is the social service and child protective service history of homicide victims? (2) Do homicide and unintentional injury deaths of children differ in their history of social service and child protective services? (3) Do the risks represented in the service contact histories of fatally injured children differ according to the homicide victim's relationship to the suspect (i.e., family vs nonfamily)?

Method

Record linkage was used to identify child homicide victims and their history of social and protective service contact. A pairwise matched case–control design was used to assess known child maltreatment history as a risk factor for homicide vs unintentional injury death.

Case and Control Subjects

Los Angeles Police Department homicide case summaries for 1978 through 1987 were reviewed; the department is responsible for investigating all deaths that might be classified as homicides in the city of Los Angeles, which has a population base of nearly 3 million. Demographic data and information about the deaths of children from birth to age 14 years were abstracted from the case summaries. A total of 220 cases were determined by the police department to be homicides; these cases make up the homicide sample for the present investigation.

For the matched-control part of the design, California Master Mortality data tapes from 1978 to 1987 (the most recent data available at the time of the study) were used. (Of the deaths labeled homicides by the Los Angeles Police Department, 89.1% were classified as homicides in the California Master Mortality database. Five percent of the total were classified as deaths due to unintentional injuries, 3.2% were classified as deaths due

Note. A one-to-one match was made on age, race/ethnicity, sex, and date of death.

FIGURE 1—Social and protective service history of 213 matched pairs of dead Los Angeles children.

to disease, and 2.7% could not be located in the database. Given that no "gold standard" exists, we chose to use the police department determination of homicide.) A Los Angeles child who had died by another sudden, traumatic means—unintentional injury—was matched by age, sex, race/ethnicity, and date of death to each homicide case. Small numbers of deaths at these ages precluded a residential match.

Exact matching was obtained for sex and race/ethnicity (Black, White, Latino, Native American, Indian, Asian). In 73.9% of the time, age matching was exact; in 97.9% of the time, ages were matched within 1 year or less. As for date of death, 97.2% of the matches died within 25 or fewer days of the death of the homicide case. Matches could not be obtained for seven cases: four newborns (Hispanic girl, Hispanic boy, Black girl, White boy), a 6-week-old Asian boy, and two East Indian boys (2 and 5 years old). Of these seven children, one died of exposure, one was pushed from a high place, one was knifed, two died of submersion, and two were beaten to death. When odds ratios are calculated, they are based on a total of 213 cases and an equal number of controls.

Protective and Social Services Contact

County government traditionally assigns the task of protecting vulnerable members of a community (e.g., children and the elderly) to a section of the county governmental structure (often the Department of Public Social Services or the Department of Protective Social Services). In a move to concentrate services for children, Los Angeles County created a separate Department of Children's Services in 1984. This department is responsible for providing and coordinating services for abused (physical and sexual) and neglected children. The Department of Public Social Services was responsible for these tasks prior to 1984 and now attends to the basic social service needs of county residents (including children) by providing food stamps and so forth. Thus, while the organizational structure of Los Angeles County services differs from that of county services in many other areas of the nation, the function of the services remains the same: attending to the needs of maltreated children and providing basic survival needs.

A court order was obtained to access the Department of Children's Services' files. Records were searched to determine whether the department had documented contact with the child or the child's family. When record linkage was established, data regarding the nature of maltreatment and of department services were abstracted. As with the cases, controls were linked with department records to determine the known history of maltreatment. Cases and controls also were linked with Department of Public Social Services records to determine if the child or the child's family had received those services. The nature of services that this department provided was recorded to ascertain whether the contact was to supply basic life necessities or to address maltreatment (as was the department's task prior to 1984). Thus, we ascertained contact with a county agency both for maltreatment/protective services and for basic social services.

Data Analysis

Summary statistics were generated to describe the child homicide victims and the unintentional injury death cases. Conditional logistic regression[19,20] for a one-to-one matched pair design was used to avoid biased parameter estimates by controlling covariates and taking into account the matching variables of age, race/ethnicity, sex, and date of death. Children with no social or protective services history served as the

reference group. Adjusted odds ratios (AORs) and asymptotic 95% confidence intervals (CIs) were calculated for the 213 pairs to measure the difference in risk between those with and those without social service or protective service histories.

Social and maltreatment programs are family-oriented services and might be more effective in preventing homicides of children by family members than in preventing those by nonfamily members. To examine this possibility, we tested whether the children who were killed differed in their history of service contact according to the victim's relationship to the suspect. A chi-square test was used to examine the homogeneity of the adjusted odds ratios obtained for homicides in which a family member was a suspect to those for homicides in which a nonfamily member was a suspect. Because a social definition of family may more accurately describe patterns of relatedness than a biological definition, especially in some racial and ethnic communities,[21] we used a social definition to encompass both biological relatives and primary caretakers (e.g., male companion of mother). Nonfamily suspects included the categories of friend/acquaintance, gang member, drug deal associate, stranger, and unknown. As noted above, the 213 matched children who died of unintentional injury served as the controls.

Results

A total of 220 children were homicide victims in the city of Los Angeles from 1978 through 1987. Modal characteristics of the victims were male sex (64.1%), Black race (49.1%), and age less than 4 years (52.3%). In 91.4% of the cases, at least one suspect was identified, most often a male (73.6%) or a family member (48.2%). The home was the most common site of the homicide (60.0%); the typical victim was shot with a firearm (32.2%) or bludgeoned (31.4%). (A complete descriptive report of child homicides in the city can be found elsewhere.[15])

Among the nonhomicide injury deaths (matched controls), transportation-related injuries were most common (71.4%). Remaining causes of unintentional injury death included burns (8.5%), asphyxiation (7.5%), falls (5.2%), and other miscellaneous means (7.4%).

A significant minority of the families of the murder victims (42.7%) and of the unintentional injury death victims (37.6%) had contact with county services sometime either before or after the child's death. Most of these cases were opened *after* the death of the child. Such action may have served to protect other children in the home but, obviously, could not have had a preventive effect for the dead child. In each type of service or combination of services, a case was more likely to be opened on the family after than before the child's death.

Prior to the death of the child, 17.4% of the homicide victims and 14.6% of the unintentional injury death children had some involvement with the county's social or child protection services. The similarity of these figures suggests that both groups of children came from troubled families. As shown in Figure 1, however, only a small proportion of the homicide cases and even fewer of the controls had a documented history of child protective services (8.0% and 2.4%, respectively).

Of the 17 (8.0%) homicide cases with some record of contact with the county owing to maltreatment prior to their deaths, 16 were also receiving social services assistance. Most (10) of the cases were receiving all of the available social services—cash, MediCal (California's Medicaid program), and food stamps. Another three families were using two of the three services. Of those receiving both child protection and social services, 12 had cases first opened regarding the social services needs. Information about the maltreatment cases (beyond presence/absence and type of record) was limited; only 5 of the 17 cases contained documentation of prior reports. Of the 8 cases that contained any information on siblings, 7 indicated the presence of siblings. After the homicide of their brother or sister, these children typically were removed from the home and placed in foster care.

Adjusted odds ratios (see Table 1) indicated that social needs alone were not related to risk of homicide (vs unintentional injury death). Homicide victims were 3.14 times as likely as unintentional injury victims to have a documented history of social and protective (maltreatment) services before their deaths. Additional analyses indicate that, when maltreatment service history was ignored, a homicide death was not associated with a history of public social services contact (AOR = 1.23; 95% CI = 0.73, 2.07). When general social service history was ignored, however, homicide cases were more likely to have had prior contact with county child protective services (AOR = 3.40; 95% CI = 1.25, 9.27).

TABLE 1—The Risk of Homicide According to Social Service Contact Prior to Death, among 213 Matched Pairs of Dead Los Angeles Children

Service Record[a]	Adjusted Odds Ratio	95% Confidence Interval
Social services only	0.82	0.44, 1.53
Protective services only	. . .[b]	. . .
Protective and social services	3.14	1.14, 8.65

[a]Children with no social or protective services history make up the comparison group.
[b]Odds ratio is undefined because one group had 0%.

One may argue that because county social and protective agencies offer family-oriented services, they might have had a more protective effect on homicides of children by family members. However, after testing the homogeneity of the adjusted odds ratios obtained for homicides in which a family member was a suspect with those for homicides in which a nonfamily member was a suspect, we found no difference by relation of the victim to the suspect.

Discussion

The present study investigates a relatively narrow research question—whether maltreatment is a risk factor specific to homicide or to child injury death in general—among 213 matched pairs of children under 15 years of age who were killed. Many of the children who died of homicide and unintentional injuries (42.7% and 37.6%, respectively) came from families who had contact with county services for child protection or for general social services. However, many of these cases were opened after the death of the child; thus, the death of the child may have alerted social services to the needs of other family members but did not serve as a preventive mechanism for the killed child. Children who died of homicide were 3.14 times as

likely as those whose deaths were unintentional to have had a documented history of both child maltreatment and social service need prior to their deaths.

Mortality risk for abused children was investigated in a recent cohort study that matched (by sex, year of birth, and county of birth) children from birth to age 18 years who were not reported to a Washington State child abuse registry to those who were.[22] Elevated mortality risk following maltreatment was evident for physical abuse and neglect across all categories of death (homicide, transportation injury, other unintentional injury, and disease). Two potential sources of bias are evident in the investigation: selection bias, in that birth certificates could not be located for over half the eligible children (11 846 of the 22 931 children reported to the abuse registry) and possible differential loss to follow-up (without an estimate of geographic mobility, one must assume that there was no differential loss to follow-up between the abused and unabused groups). In other words, the fact that a death certificate was not found does not necessarily mean that the child did not die; rather, it means that the child did not die in the state of Washington. Furthermore, an indicator of the time elapsed between the report of the abuse and the deaths would have provided important information about whether time at reporting is a relevant factor for intervention. Sabotta and Davis[22] conclude that, although intervention by the appropriate government agency does not reduce the risk of death among abused children to that among nonabused children, risk may be even higher without such intervention.

The present investigation adds two pieces of information not available in the Sabotta and Davis study: race/ethnicity of the child and relationship between the child victim and suspect. First, matching on race and ethnicity eliminates the possibility of a spurious association between reports of abuse and homicide; however, the present study shares a limitation with Sabotta and Davis in that socioeconomic information was not available. Second, examining the relationship of the victim to the suspect (i.e., family member vs non–family member) indicates that risk of homicide vs unintentional injury death is not related to the relationship of the victim to the suspect.

Two issues are central in interpreting the finding of no difference between risk of death by a family member and that by a nonfamily member: the nature of the services provided and the maltreatment issues reported to the agency. First, child protection services are family oriented and include the power to remove children from an abusive home. Thus, a documented maltreatment history may not place a child at increased risk for homicide death at the hands of a family member because those children most at risk have been removed from the abusive environment. Additional research is needed to address this important issue. One can note that a history of contact with county protective services does not decrease a child's risk of homicide death to that of a fatal unintentional injury, either. Second, one must recall that child protective services are extended to neglected as well as abused children. Lack of adequate supervision (one aspect of neglect), which, for example, could allow a relatively young child to be outdoors in an area frequented by gangs late at night, may increase a child's risk of homicide by someone outside the family yet still be linked to parental care issues. In this manner, a history of child maltreatment that had come to the attention of county services could be linked to an increased risk of child homicide (compared with a fatal unintentional injury) at the hands of a nonfamily member.

Study Limitations and Suggestions for Future Research

Although documented maltreatment was found to be associated with increased risk of homicide in this investigation, causal factors were not ascertained. Documented maltreatment may serve as a proxy for other factors, including but not limited to socioeconomic status, substance use by caretakers, and family disruption and discord.

The difficulty of selecting appropriate controls is well documented, and we acknowledge that some of the matched controls actually may have been unrecognized homicide victims. For example, a portion of the asphyxiation deaths that were labeled unintentional may have been intentional strangulations. (Child death review teams may enhance consensus on which cases of child death are labeled homicide.[23–25]) Such potential misclassification error would reduce the likelihood of detecting differences between the groups because deaths that actually were homicides would be included in the controls; thus, misclassifying homicides as unintentional injury deaths would underestimate the effect.

Under ideal circumstances, which would include greater resources for research and unlimited access to service delivery systems, several control groups could be used in an effort to detect additional differences (see, e.g., the work of Haddon and colleagues[26]). Depending on the research question, additional control groups could be made up of children who died of noninjury causes, living children with nonfatal intentional injuries, living children with nonfatal unintentional injuries, uninjured living children, and other groups. Investigators must be sensitive, however, to the strain that research activities place on an already overburdened service delivery system.

The present research has limited applicability to the homicide of infants. Matches could not be obtained for any of the newborns, who accounted for four of the seven cases that could not be matched. Risk factors for the homicide of newborns probably follow patterns different from those for the homicide of older children.[27,28]

Implications

Children are a unique segment of our population in that specialized services such as foster care and child abuse prevention agencies have been developed for and are available only to them. Secondary prevention services (e.g., home visitor programs) targeting services to specific high-risk groups have been shown to maintain the family and to reduce abusive behaviors toward children.[29–31] However, identifying family structure variables associated with child homicide remains a complex task.[32] High-risk groups must be identified in sufficiently specific terms so that, barring an influx of additional resources, the limited funds currently allocated for such services can be applied where most needed.

It is crucial to note that the great majority of children who died of homicide during the study period had no prior contact with child protective services. Most current systems of child protection target services to the victims of child abuse with the goal of minimizing the impact or negative consequences of abuse. At least two assumptions limit the applicability of this primarily tertiary prevention approach: first, that all abused children are detected, and second, that abuse is repetitive. Protection services will be successful only to the extent that

abused children are identified and given helpful services. However, we know that many maltreated children are not detected. Moreover, if some children are victims of single violent (and fatal) episodes, traditional social service intervention is not likely to have a preventive impact simply because such cases are not identified until it is too late.

In addition to exploring new mechanisms to detect children at risk of homicide, existing service delivery systems may serve a unique preventive function. One innovative program uses animal control and state humane officers, who have 24-hour staff and are often allowed to make unannounced visits to a home in which an animal was mistreated, to identify potentially abused children (K. White, Humane Society of the United States, personal communication, June 1993). However, the ability of this program to detect abused children and prevent further maltreatment (and perhaps homicide) remains to be tested.

These recommendations may be of assistance in addressing the homicide risk of some children and do not preclude other public health efforts to reduce homicides. Social, product, legislative, law enforcement, mental health, and other approaches are needed to meet the complex public health challenge presented by the homicide of children. □

Factors That Influence Clinicians' Assessment and Management of Family Violence

Virginia P. Tilden, DNSc, RN, Terri A. Schmidt, MD, Barbara J. Limandri, DNSc, RN, Gary T. Chiodo, DMD, Michael J. Garland, DScRel, and Peggy A. Loveless, MSW, LCSW

ABSTRACT

Objectives. High rates of family violence and low rates of detection, report, and therapeutic intervention by health professionals are well documented. This study was undertaken to determine what factors influence clinicians' decision making about identifying abuse and intervening with victims.

Methods. Survey data about clinicians' experiences with and attitudes toward family violence were gathered by mailed questionnaire from a random sample of practicing clinicians in six disciplines (n = 1521).

Results. Data showed similarities within and wide differences among three groups of subjects: dentists/dental hygienists, nurses/physicians, and psychologists/social workers. Overall, a third of subjects reported having received no educational content on child, spouse, or elder abuse in their professional training programs. Subjects with education on the topic more commonly suspected abuse in their patients than those without; among all subjects, spouse abuse was suspected more often than child abuse while elder abuse was suspected infrequently. Significant numbers of subjects did not view themselves as responsible for dealing with problems of family violence. Subjects indicated low confidence in and low compliance with mandatory reporting laws.

Conclusions. There is a need for educators to expand curricula on family violence and for legislators to reexamine mandatory reporting laws. (*Am J Public Health.* 1994; 84:628–633)

Introduction

Recent reports in the medical literature document that the incidence of family violence is much greater than has been assumed in the past and that health professionals tend not to screen patients for abuse.[1–4] Statistics indicate that between one fourth and one half of all intimate couples are violent at some time,[5] and that, annually within families, 3 to 4 million women are battered,[4] 1.5 million children are seriously abused, another 5 million children are maltreated,[6,7] and 2.5 million elders are abused or neglected.[8] These documented rates are likely to be underestimates because surveys typically do not include non-English-speaking persons, the very poor, those without telephones, and those in hospitals or other institutions.[4]

Victims of abuse present for treatment in clinical settings—both for their injuries and for health problems related to stress (e.g., anxiety, insomnia)—in numbers much greater than health professionals believe. For example, one third of women who visit hospital emergency departments do so because of symptoms related to ongoing abuse from their intimate partner,[9–11] and one sixth of pregnant women in public prenatal clinics have been abused within the past year.[12] Characteristically, victims of family violence do not disclose their abuse.

Thus, although health professionals often treat abused patients, in the vast majority of treatment situations they fail to suspect abuse.[9,10,13–15] When they do suspect it, the degree to which their responses are therapeutic or even compliant with state mandatory reporting laws varies widely.[16] The failure of clinicians to report suspected cases is well documented[16–26] and has been attributed to numerous causes, such as uncertainty about the clinical evidence, misgivings about the actions of protective services, and fear of involvement in court proceedings.[19,23,27–33]

While there has been some discipline-related empirical research on factors related to clinicians' unwillingness to detect and intervene in abuse,[1] there are little comparative data among the health professions on such factors. The aim of this study, therefore, was to explore factors, such as gender and training, that are likely to influence clinicians' assessment and management of abuse victims, and to examine factors within and among the disciplines of dentistry, dental hygiene, medicine, nursing, psychology, and social work. Practitioners within these six clinical disciplines have the opportunity and the responsibility for making clinical judgments about abused patients. Reported here are results of a mailed survey that was part of a larger study that included interviews with practitioners to explore their ethical reasoning when faced with evidence of domestic violence.

Methods

A mail survey was designed by the investigators to measure factors related

Elder abuse	17	11	43	24	25	45	27

to clinicians' assessment and management of suspected abuse. Literature related to decision making about abuse[21,24–30] guided the development of survey items. The four-page survey included (1) demographic items (respondent's discipline, gender, and year of graduation); (2) items that tapped subjects' recall of the amount of educational content about family violence they received in their professional training programs (scored as none, a little, a moderate amount, or a great deal); (3) frequency with which subjects suspect that their patients have been abused (scored as never, occasionally, a moderate amount, or frequently); (4) subjects' typical responses or interventions when abuse is suspected (from a checklist of typical interventions); and (5) attitude items regarding both their extent of responsibility in dealing with domestic violence and mandated reporting. The survey was pilot tested initially with two or three clinicians in each of the six disciplines and was then revised. The revised form was retested with a sample of 30 clinicians, 5 in each discipline, selected from a health sciences university directory. Twenty-seven responses were received, and inspection of them led to final changes in the survey. Time to complete the survey averaged 10 minutes in pilot tests.

Following University Institutional Review Board approval, the survey was mailed to 2100 health care professionals (350 practitioners in each of six health care disciplines) who represented a random sample of professionals with licenses to practice in a northwestern state. Surveys were mailed under a cover letter that was tailored slightly to each discipline and signed by the member of the research team from that discipline. Returns were tracked by a research assistant. Nonresponders at 2 weeks were sent a reminder postcard; 4 weeks after the initial mailing, nonresponders were sent a second survey. Mailing lists were then destroyed.

Data were analyzed with the Crunch 4.0 statistical software package. Descriptive (central tendencies, frequencies) and inferential (correlation, chi-square, logistic regression) statistics were computed.

Results

Of the 2100 questionnaires mailed, 1588 were completed and usable, 53 were returned as undeliverable, and 3 were returned as addressee deceased. The overall response rate was 78%; however, response rates for the specific disciplines varied (dental hygienists, 83%; social workers, 82%; psychologists, 81%; nurses, 78%; dentists, 78%; physicians, 69%). Sixty-seven people reported retirement and their responses were excluded, leaving 1521 questionnaires for analysis. Surveys contained little missing data, probably owing to the extensive pilot testing that went into formatting items and response choices to minimize the burden of responding. The small amount of item-level missing data that occurred is reflected in the slightly different sample numbers reported on the individual items as noted in the tables.

Sample Characteristics

Sample characteristics are presented in Table 1. The overall sample included a slightly higher proportion of women than men although, as expected, the gender proportions in individual disciplines were quite skewed. The median year of graduation from their respective professional training was 1977, and time since graduation ranged from 1 to 49 years, with a median of 14 years. Overall, 76% of survey subjects came from urban counties, which reflected regional population demographics in

TABLE 3—Percentage of Subjects Who Reported Commonly Suspecting Physical or Sexual Abuse among Patients

	Dental Hygienists (n = 271)	Dentists (n = 247)	Nurses (n = 236)	Physicians (n = 218)	Psychologists (n = 260)	Social Workers (n = 269)
Child abuse

Elder		
Physical (n = 1453)	2.10	1.20, 3.69
Sexual (n = 1441)	1.24	0.53, 2.93

that 75% of the population in the northwest region resides in urban counties. In subsequent analyses, however, there were no statistically significant differences between urban and rural subjects on any of the study variables.

Education

The extent of subjects' formal education (i.e., excluding postgraduate continuing education) on the topic of domestic violence varied widely according to discipline and year of graduation. Table 2 shows the percentage of subjects reporting any (i.e., a little, a moderate amount, or a great deal) educational content on child, spouse, and elder abuse in their professional training programs.

Combining groups, 64% of subjects reported education in child abuse, 40% reported education in spouse abuse, and 27% reported education in elder abuse. Of the total sample, 33% (n = 499) reported no education in any of these three types of abuse. Examining subjects by discipline, social work had the highest proportion of subjects reporting any education in each type of abuse, and dentists and dental hygienists had the smallest proportion. For all types of abuse, the percentage of subjects who reported any education increased as year of graduation became more recent.

Suspecting Abuse

Subjects were asked how often they suspected that a child, adult, or elderly patient had been a victim of physical or sexual abuse. Table 3 shows the percentage of subjects who indicated that they suspected abuse either a moderate amount or frequently, combined here as commonly. In general, the numbers of subjects who commonly suspected abuse were low in all disciplines except social work and psychology. Generally, subjects were most likely to suspect physical abuse of spouses, followed by physical or sexual abuse of children. Elder abuse, either physical or sexual, was not frequently suspected by any discipline.

Subjects who reported receiving any educational content on family violence in their training programs were more likely to indicate that they commonly suspected child, adult, and elder abuse, both physical and sexual, among their patients. For example, among those with education, 19.0% and 20.6% commonly suspected physical and sexual child abuse, respectively, while among those without education, the proportions were 6.6% ($P < .001$) and 7.2% ($P < .001$), respectively. This statistically significant effect of education on suspicion of abuse held true for spouse and elder abuse as well.

We used logistic regression to test the association between educational content on domestic violence (dichotomized as none vs any) and suspicion of abuse while controlling for the possible confounding variables of gender, year of graduation, and discipline. Results are shown in Table 4.

Education predicted more than one-and-a-half times the rate at which physical and sexual child abuse was suspected and more than twice the rate at which physical abuse of elders was suspected. However, education did not strongly influence suspicion of spouse abuse or sexual abuse of elders. It may be that sexual abuse of elders is relatively infrequent, which would thus limit the extent to which factors such as education would influence any suspicion of its occurring. Yet it is clear that education, entirely apart from other factors, positively affects the rate at which clinicians suspect child and physical elder abuse.

Interventions

We asked the clinicians the extent to which they view themselves as responsible for intervening in suspected domestic violence. Responses to the attitude item "Professionals in my discipline have as much responsibility to deal with problems of family violence as they do to deal with other clinical problems" indicated that, although the majority of clinicians agreed with the statement, remarkably large numbers in some disciplines, especially dental hygiene and dentistry, did not agree (dental hygienists, 45.9%; dentists, 47.3%; nurses, 13.3%; physicians, 15.4%; psychologists, 1.5%; social workers, 2.6%).

From a list of interventions, subjects were asked to choose their typical responses when they encounter an adult, child, or elder whom they suspect of having been abused. Table 5 presents the interventions selected most often by subjects in each discipline. Reporting was rarely the most common intervention for clinicians in any discipline even

TABLE 5—Most Frequently Selected Intervention[a] for Child, Spouse, and Elder Abuse

	Dental Hygienists (n = 275)	Dentists (n = 250)	Nurses (n = 241)	Physicians (n = 220)	Psychologists (n = 261)	Social Workers (n = 273)
Child abuse	Consult (39%)	Chart and observe (45%)	Consult (34%)	Report (39%)	Discuss with family (44%)	Report (59%)
Spouse abuse	Discuss with patient (26%)	Discuss with patient (39%)	Consult (51%)	Discuss with patient (75%)	Discuss with patient (77%)	Discuss with patient (78%)
Elder abuse	Chart and observe (21%)	Chart and observe (24%)	Consult (52%)	Discuss with patient (41%)	Discuss with patient (15%)	Discuss with patient (23%)

[a]Choices included (1) make a note in the chart and observe over time; (2) discuss the observations with the patient; (3) discuss the observations with family members; (4) consult with another professional; (5) refer the patient to social service/mental health service; (6) report/encourage patient to report to appropriate protective service agency or to police; (7) facilitate arrangements for safety; (8) elect not to intervene; or (9) other.

though mandated reporting laws for child and elder abuse have existed in the state since 1971 and 1981, respectively. Only among social workers and physicians was reporting selected most often and then only for child abuse.

In addition to these significant differences among disciplines in choice of intervention, gender affected the frequency with which subjects consulted with another professional. For all types of abuse (child, spouse, and elder), women were more likely than men to consult with another professional ($P < .001$ for each). Using logistic regression to test the effect of gender on choice of intervention while controlling for discipline, we found significant gender differences in some of the interventions selected for child abuse and spouse abuse but not for elder abuse. For child abuse, women were almost twice as likely as men to consult with another professional (adjusted odds ratio = 1.94; 95% confidence interval [CI] = 1.33, 2.82). Also, women were one and a half times more likely than men to report abuse to child protective services (adjusted odds ratio = 1.66; 95% CI = 1.05, 2.61). For spouse abuse, women were one-and-a-half times more likely than men to consult with another professional (adjusted odds ratio = 1.52; 95% CI = 1.08, 2.13), while men were one-and-a-half times more likely than women to discuss the observations with a family member (adjusted odds ratio = 1.61; 95% CI = 1.08, 2.44).

Next, we used logistic regression to examine the effect of educational content on choice of interventions while controlling for the effects of gender, year of graduation, and discipline. Education significantly predicted the choice of one intervention in child abuse (make a note in the chart and observe overtime [adjusted odds ratio = 1.42; 95% CI = 1.00, 2.03]); of three interventions in spouse abuse (make a note in the chart and observe [adjusted odds ratio = 1.41; 95% CI = 1.05, 1.89], discuss observations with family [adjusted odds ratio = 1.75; 95% CI = 1.19, 2.59], and consult with another professional [adjusted odds ratio = 1.58; 95% CI = 1.16, 2.15]); and of four interventions in elder abuse (make a note in the chart and observe [adjusted odds ratio = 2.4; 95% CI = 1.58, 3.63], discuss observations with patient [adjusted odds ratio = 1.51; 95% CI = 0.99, 2.28], discuss observations with family [adjusted odds ratio = 1.61; 95% CI = 1.06, 2.45], and report to appropriate protective service agency [adjusted odds ratio = 1.57; 95% CI = 1.00, 2.46]). An interesting feature of these findings is that formal educational content in family violence significantly predicted the reporting only of elder abuse.

TABLE 6—Subjects' Attitudes (%) toward Mandatory Reporting Laws for Child, Spouse, and Elder Abuse

	Dental Hygienists (n = 275)	Dentists (n = 251)	Nurses (n = 241)	Physicians (n = 221)	Psychologists (n = 261)	Social Workers (n = 273)
Child abuse: laws are effective	36	37	39	46	50	52
Spouse abuse: there should be a law	66	55	76	56	48	68
Elder abuse: laws are effective	33	32	35	35	39	38

Mandated Reporting: Compliance and Attitudes

Of those clinicians who indicated that their practices included children, the percentage who included reporting in the list of interventions they typically used varied (dental hygienists, 8.8%; dentists 20.9%; nurses, 44.4%; physicians, 74.5%; psychologists, 73%; social workers, 87.5%). Of those clinicians who indicated that their practices included the elderly, the percentage who included reporting among interventions they used also varied (dental hygienists, 6.5%; dentists, 12.2%; nurses, 32%; physicians, 45.5%; psychologists, 60.8%; social workers, 76.4%).

These relatively low rates of reporting are reflected in subjects' attitudes about the effectiveness of mandatory reporting, which are presented in Table 6. Only about one third of subjects in each discipline thought that mandatory reporting of suspected elder abuse is effective in dealing with the problem.

Approximately half of the physicians, psychologists, and social workers thought that mandatory reporting of suspected child abuse is effective in dealing with that problem, as did smaller percentages (37% to 39%) of dental hygienists, dentists, and nurses. Despite doubts about the effectiveness of mandatory reporting of suspected child and elder abuse, a majority of subjects in all disciplines except psychology thought there should also be a mandatory reporting law for spouse abuse; more women than men held this opinion as well (69% vs 53%, $P < .001$). We used logistic regression to assess the effect of educational content on subjects' attitudes about mandatory reporting laws while controlling for gender, year of graduation, and discipline. In this multivariate model, there were no significant effects of the independent variables on attitudes about reporting.

Discussion

Although it is difficult to isolate factors that relate to clinicians' responses to victims of family violence, certain trends in the data may be of value to educators and legislators. First, there are similarities within and wide differences among three groups of subjects: dentists/dental hygienists, nurses/physicians, and psychologists/social workers. This fact, when combined with the low rate of education on family violence in professional training programs, indicates that clinicians' responses may stem more from their disciplinary background than from knowledge about family violence. Given that clinicians in all six disciplines are about equally exposed to the public and equally responsible for detecting, reporting, and responding to violence, the lack of similarity in responses across disciplines and the discipline-specific patterns are disturbing.

A second disturbing finding is the high numbers of currently practicing clinicians without education about this highly prevalent health problem. Fully one third are without education in *any* of the three main types of domestic violence. Beyond that, approximately one third are without education in child abuse, two thirds are without education in spouse abuse, and three quarters are without education in elder abuse. Although the trend toward more education among more recent graduates is encouraging and consistent with the literature,[14] the findings nonetheless point to an enormous lack in professional training programs. That approximately one half of graduates since 1980 reported no education in spouse or elder abuse and a fifth reported no education in child abuse are startling findings, given that it was in the early 1980s that Surgeon General C. Everett Koop called for increased national attention to domestic violence as a major public health problem.[34]

The issue of education is especially important given the influence it exerts on the rates with which clinicians suspect abuse, an influence that is separate from that exerted by other variables, specifically gender, recency of graduation, and discipline. Although, the findings overall show low rates of suspecting abuse, clinicians with education do suspect abuse more commonly.

Authors in the recent literature have called for major revisions in child abuse curricula for medical[35–37] and dental students.[21,38] We found greater gaps in education about spouse and elder abuse, and therefore we expand that call to include even more extensive revisions in curricula for all health professionals focused on abuse in these areas. There appears to be a disproportionate emphasis in education on child abuse, probably because it presents a clearer model of victim and abuser. The result is that health professionals often lack an understanding of the more complicated dynamics associated with the abuse of adults, such as reasons why victims often stay in abusive situations. This may be a factor in clinicians' less therapeutic response to battered women, as noted in prior literature.[16]

A third disturbing finding is that large numbers of health professionals in each discipline believed abuse to be infrequent among their patients. These findings support those of prior studies.[9,10,13–15] Abuse is a hidden health care problem, and the unsuspecting stance of health professionals allows the problem to remain undetected much of the time.

Dentists and dental hygienists reported the least education in abuse, the least frequent rate of suspecting abuse, and the greatest proportion who do not see themselves as responsible for intervening into suspected abuse. We encourage dentistry and dental hygiene to recognize that injuries to the teeth, jaw, neck, and oral soft tissues are common indicators of abuse, and that dentists and hygienists often have the first opportunity to observe these symptoms.[39]

The question of how clinicians choose to intervene showed trends reflective of gender-based reasoning styles noted by others.[40] Gender influences how clinicians prefer to handle suspected child and spouse abuse cases, with women preferring the more collaborative approaches of consulting with others and reporting to others, and men preferring to handle things alone by discussing the problem with the family. Although we hesitate to place a value judgment on styles, we do call for increased collaboration and communication between health care team members in order to combat the isolation that tends to suppress suspicion of and intervention in cases of abuse.

Significant numbers of professionals do not view themselves as responsible for intervening, and those who do intervene tend not to report abuse to the appropriate authorities. This issue of attitudes about and compliance with mandatory reporting laws deserves a great deal of reflection. The vast majority of dental hygienists and dentists, over a half of the nurses, and a quarter of the physicians said they would *not* report a case of suspected child abuse to authorities; even greater numbers said this about suspected elder abuse. Although those with more education more commonly *suspect* abuse, education does not influence their *reporting* of abuse. Subjects indicated low confidence in mandatory reporting, which their noncompliance reflects. Despite this, a majority indicated a wish for a mandatory reporting law for suspected spouse abuse, reflecting the human tendency to wish for external solutions even in the face of negative evidence.

In our discussions with clinicians, many said the primary reason they avoid reporting is because doing so sets into motion a series of events that unfold out of their control and are often counter-therapeutic. Thus, clinicians may experience an ethical dilemma between their perceived duty to report and their low confidence in the system's ability to respond effectively. This untenable position likely contributes to the large numbers of health professionals who say they do not suspect abuse, given that denial is one solution to an ethical dilemma. State officials and legislators should consider the problem of underfunding and overloading of protective services vis-à-vis clinicians' low level of

confidence and their resulting noncompliance with statutes. Many clinicians would prefer that reporting be mandatory for nonclinical professionals (e.g., teachers) or nontreating clinicians (e.g., office nurses) but that treating clinicians be allowed a margin of discretion regarding the most therapeutic intervention.

Findings of this study are limited by the restriction of the sample to the northwestern region, to problems associated with retrospective recall inherent in surveys, and to the effects of history during data collection. Regarding the latter, subjects' responses may have been affected by problems within child protective services that were covered widely in the news media during the period of data collection. Even so, trends in the data are sufficiently strong to inform educators of the need for expanded curricula on family violence and to inform legislators of the need to reexamine mandatory reporting laws relative to available protective services. □

Suicidal Ideation and Attempts among Chemically Dependent Adolescents

Eva Y. Deykin, DrPH, and Stephen L. Buka, ScD

ABSTRACT

Objectives. Suicidal ideation and attempts were examined in a population of chemically dependent adolescents, a group at high risk of self-destructive behavior.

Methods. The prevalence and correlates of suicidality and of major depressive disorder were assessed by the Diagnostic Interview Schedule and a structured family and social history interview with 300 addicts aged 15 through 19 years.

Results. Suicidal ideation was reported by 31% to 75% of the subjects and suicide attempts were reported by 28% to 61%, with females predominating. Thoughts of suicide combined with prolonged thoughts of death in general and a desire to be dead were highly associated with suicide attempts. Exposure to physical or sexual abuse was associated with a significantly increased risk of suicide attempts for males but not for females.

Conclusions. The probability of a suicide attempt increases when thoughts of suicide coincide with morbid ideation of extended duration, suggesting that risk assessment should be based on duration as well as presence of morbid thoughts. Substance abuse treatment requires an assessment of suicidal potential and counseling for those whose potential is high, with special attention to males exposed to abuse. (*Am J Public Health.* 1994;84:634–639)

Introduction

The dramatic rise in suicide among adolescents over the past quarter-century has not been matched by similar changes in other age groups. During the period 1960 through 1988, when the rate of suicide for persons aged 15 through 24 more than doubled from 5.2 to 13.2 per 100 000, the rate of suicide among those aged 45 through 64 decreased from 20.7 to 14.6 per 100 000 and the rate among those aged 75 through 84 decreased from 27.9 to 25.9 per 100 000.[1] Furthermore, a population study by Murphy and Wetzel[2] indicated that in the past 40 years, each cohort entering adolescence had a higher rate of suicide than the preceding cohort and this difference increased as each cohort aged through adolescence. This disparity among age groups suggests that the factors responsible for the increase in adolescent suicide either preferentially affect the young or are absent at older ages. Among the influences thought to have particular relevance for suicidal behavior in adolescence are increased competition for diminished resources,[3] exposure to child abuse,[4,5] high incidence of family fragmentation,[6–8] elevated occurrence of depressive illness in cohorts born after 1935,[9] greater availability of handguns,[10–14] and increased use of alcohol and other drugs.[10–15]

Substance use may be especially important in the development of suicidal and other self-destructive behaviors. Mind-altering substances tend to disinhibit impulsivity and facilitate the expression of suicidal impulses that might otherwise have been contained. In addition, substance abuse can result in social isolation and increase the risk of depressive mood by distancing an adolescent from family or by diminishing his or her opportunities because of school failure, lost jobs, or legal involvement. Lastly, chemical dependence may place the adolescent in close contact with drug dealers and users who have easy access to handguns. The combination of substance abuse and availability of handguns poses an especially high-risk situation.

A substance-abusing population is particularly informative for the study of adolescent suicidal behavior and ideations. Self-destructive ideation, behavior, and suggested risk factors are common among this population,[15] making it a useful group for empirical inquiry. Furthermore, this is a population with identified service needs that would benefit from improved prediction and treatment methods. Lastly, focusing on subjects at the extreme end of the substance-abusing spectrum, results from this population could provide useful information for preventive strategies among adolescent substance abusers who have not yet reached the level of chemical dependence.

The purpose of this study was threefold: first, to ascertain the prevalence of various forms of morbid/suicidal ideation and of suicide attempts among a group of adolescents who meet DSM-III-R criteria for chemical dependence[16]; second, to examine the relationship of various types of morbid ideation to the occurrence of suicidal attempts; and third, to assess selected social and

demographic characteristics, including a history of victimization, as possible predictors of suicide attempts.

Sample and Settings

The study sample consisted of 300 adolescents (224 males, 76 females) aged 15 through 19 who were receiving residential treatment for their dependence on alcohol or other drugs. This sample was assembled during the course of a larger study of the prevalence and correlates of psychiatric and physical comorbidity among chemically dependent adolescents. Subjects were enrolled in the study from seven of eight Massachusetts treatment sites that were closely affiliated with the Massachusetts Department of Public Health and that had residential treatment programs designed for adolescents. The eighth treatment center chose not to participate in the study. The cost of care for most of the adolescents at these facilities was covered by Medicaid or by state funds through the Department of Public Health. The eligible study sample thus included consecutively admitted adolescents receiving state support for residential treatment for chemical dependence.

The seven facilities provided treatment modeled after the Alcoholics Anonymous 12-step program, which emphasizes clearly defined rules and expectations in conjunction with graded levels of responsibility and freedom. The treatment focused on behavior modification rather than on psychiatric morbidity, and, as a matter of policy, the treatment sites refused admission to youths who had florid psychiatric symptoms. We enrolled willing subjects into the study between the 1st and 4th weeks of treatment. For adolescents who were younger than 18 years and who were not medically emancipated, we obtained signed consent from their parents as well. The institutional review boards of the Harvard School of Public Health and the Massachusetts Department of Public Health and the directors of all seven treatment sites approved the study protocol, the methods of obtaining informed consent, and the content of the consent statement. Eligible subjects who refused to participate (18%) were almost identical to enrolled subjects with respect to age, gender, and race, suggesting that the study sample is representative of eligible adolescents at the treatment sites.

[a] *df* = 1 unless otherwise noted.
[b] Determined by the Hollingshead Index.[21] Class I = most advantaged; Class V = least advantaged.

Methods

We obtained information on suicidal ideation and suicidal attempts by means of the Diagnostic Interview Schedule (DIS), Version III-R,[17] a validated, structured interview that ascertains the prevalence of psychiatric disorders according to DSM-III-R criteria. Interviewers were college graduates who had previously worked with adolescents and who successfully completed two weeks of training in the administration and coding of the DIS. Training included background on the structure and purpose of the DIS, mock interviewing and coding, homework exercises, and finally actual interviews with the trainer present. Regular meetings were held throughout the study period to review interview techniques and to ensure that interviewers did not stray from the established protocol.

The section of the DIS that assesses major depressive disorder includes questions on the occurrence of three forms of morbid or suicidal ideation, as well as on the occurrence of a suicide attempt. The questions were as follows: (1) "Has there ever been a period of *2 weeks or longer* when you thought a lot about death, your own, someone else's, or death in general?" (2) "Has there ever been a period of *2 weeks or longer* when you desired to be dead?" (3) "Have you ever thought of committing suicide?" (4) "Have you ever attempted suicide?" The first two questions differed from the last two in that they specified a duration, whereas the last two inquired about any occurrence. Each question elicited a yes or no answer. Data on sociodemographic characteristics and on victimization were obtained by a structured interview also administered at the time of the subject's enrollment into the study. Information on parents' substance abuse and psychological problems was obtained from the subjects and not by direct examination of the parents. Data on parents' psychological problems were elicited by the follow-

ing questions: "Has your father (mother) ever had a psychological or emotional problem? Has he/she ever received treatment for this problem?" Only parents who were reported as having received treatment were classified as having a psychological difficulty. Similarly, parental alcohol and drug use was determined by the following question: "Has your father (mother) ever been treated for his/her use of alcohol (drugs)?" We assessed victimization by subjects' answers to four questions: (1) whether a report of child abuse or neglect had ever been filed with a child protective agency on behalf of the subject or any sibling; (2) whether the subject had ever experienced physical abuse; (3) whether the subject had ever been subjected to sexual abuse; and (4) whether the subject had ever been removed from the home by authorities of the child protective system. Each question elicited a yes or no answer.

Data were analyzed by SAS.[18] Associations of suicide attempts with morbid ideation, gender, and history of victimization were assessed by point estimates and confidence intervals of relative risks. All analyses were done separately for each gender and then for the total sample, controlling for gender with the Mantel-Haenszel summary relative risk statistic.[19] *P* values were computed by the Cochran-Mantel-Haenszel statistic.[20]

Results

Characteristics of Subjects

Table 1 shows the personal characteristics of the study subjects for each gender. Despite representation of all socioeconomic groups as determined by the Hollingshead Four-Factor Index,[21] the sample was largely a disadvantaged one characterized by a high degree of welfare recipiency, parental alcohol and drug abuse, parental emotional or psychological problems, and a high prevalence of victimization among the subjects. Males were significantly more likely than females to be at least two grades below their age-appropriate level and to meet DSM-III-R criteria for dependence on both alcohol and drugs. Females were more likely to report at least one parent with psychological or emotional problems and to have been victimized through physical and sexual abuse.

Prevalence of Morbid Ideation and Suicide Attempts

Table 2 shows the reported prevalence of the three types of morbid ideation and of suicide attempts. Females were almost twice as likely as males to have experienced each type of ideation and were more than twice as likely to have made a suicide attempt. Table 3 shows the proportion of subjects who had made a suicide attempt among those reporting no, one, two, or three types of morbid ideation. For both genders, the proportion of subjects attempting suicide increased with the number of thoughts experienced. The increase was slightly but not significantly more marked among females. Only in the extreme group of those who had experienced three types of ideation were females significantly more likely to be suicide attempters. These data suggest that both gender and the number of types of ideation play a role in the development of a suicide attempt but that female gender has its greatest impact only when all three types of ideation are present.

Type of Morbid Ideation as a Predictor of a Suicide Attempt

The most sensitive predictor of a suicide attempt was having experienced a thought of suicide, which was present among 98% of the suicide attempters. However, since the thought of suicide was also reported by 38% of nonattempters, this type of ideation was not specific to attempters. For the entire sample, the risk of a suicide attempt among those who experienced a thought of suicide was only 59%. We therefore investigated whether the risk of a suicide attempt varied when a thought of suicide occurred with and without the other two types of morbid ideation. When a thought of suicide was experienced with neither of the other two types of ideation, the probability of an attempt was 44.4%. It remained at approximately this level when it occurred only with thoughts of death in general (40.0%) and when it was present with only a desire to be dead (42.9%). However, when a thought of suicide co-occurred with both of the other types of ideation, the risk of a suicide attempt was elevated to 74.5%. The data in Table 4 show that although a thought of suicide, either alone or in

combination with one other type of ideation, elevates the risk of suicide to between 16 and 18 times that of subjects without such a thought, the combination of all three types of ideation nearly doubles the elevated risk to 30-fold. These data indicate that although a thought of suicide is in itself an important risk factor for a suicide attempt, its impact is greatly magnified when it is joined by the other two types of ideation.

Since depressive illness is both a known cause of suicide and a concomitant of morbid thoughts, it was necessary to control for depressive illness to obtain an unconfounded measure of the association of morbid thoughts with suicide attempt. Lifetime prevalence of major depressive disorder was obtained by means of the DIS according to DSM-III-R criteria and was found to be positive in 78 of the 300 study subjects (28%). Table 5 shows that when major depressive disorder was controlled, the association of the three types of ideation with attempted suicide still held, indicating that these thoughts constituted an independent risk factor for attempted suicide apart from that imposed by depressive illness. In fact, the combination of the three types of ideation proved to be a better screen for a suicide attempt than the diagnosis of major depressive disorder. When the diagnosis of major depressive disorder was used as the screen for attempted suicide, its sensitivity was 46.7%, its specificity was 86%, and its predictive value was 65.4%. In comparison, the combination of the three types of ideation had values of 64.2%, 87.2%, and 74.5%, respectively, for the same screening parameters.

Suicidal Behavior and Victimization

Table 6 presents the association between attempted suicide and various aspects of victimization. The prevalence of all four indicators of victimization was very high in the total sample, ranging from a low of 25% for removal from the home to a high of 45% for physical abuse (see Table 1). All aspects of victimization were more common among females; the greatest gender difference was found for sexual abuse (72% of females vs 10% of males).

For females, exposure to victimization did not increase the risk of a suicide attempt. However, males who had been exposed to physical or sexual abuse or who stated that a report of abuse or neglect had been filed with authorities were between 1.8 and 2.4 times more likely than males without such exposures to have made a suicide attempt. In all instances, this elevation of risk for males was statistically significant. Finally, removal from the home by protective authorities was not associated with a suicide attempt in either gender or for the total sample. However, since removal from the home may occur for a variety of reasons, we reassessed its association with suicide attempt only among those 147 subjects who had experienced some form of victimization. Surprisingly, in this restricted sample, removal from the home was not significantly associated with attempted suicide. Those who had been removed from home had only a 33% greater risk of having made a suicide attempt ($\chi^2 = 2.72$, $P = .10$).

TABLE 4—Risk of Attempted Suicide, by Type of Morbid Ideation

Note. Owing to lack of information, three subjects could not be evaluated for major depressive disorder.

Discussion

The prevalence of suicidal ideation and of suicide attempts in this population of substance-dependent youths is between five and seven times that found in other cross-sectional studies of community samples.[22-24] Because of differences in methods of data collection, wording of questions, source of study subjects, and subjects' characteristics, comparisons among groups are difficult. However, a previous cross-sectional study

of 424 college freshmen aged 16 through 19 years that used the same data collection instrument reported a prevalence of attempted suicide of 3.5%, or 1/10 the prevalence found in the present study.[23] In the college study, there were 40 students who met DSM-III criteria for substance abuse, including 4-(10%) who reported having made a suicide attempt. Among the 384 students who were not substance abusers, the suicide attempt rate was only 2.6%. The data from that study as well as those from the present study provide evidence for an increased risk of suicidal behavior among youth with severe substance involvement.

The cross-sectional nature of this study does not provide data on whether morbid ideation preceded or followed a suicide attempt. The strong associations between these variables indicate that they are not independent of one another, but the associations do not inform as to their relative occurrence. Conventional wisdom would suggest that morbid ideation is more likely to precede a suicide attempt rather than the other way around. However, the temporal sequence of these variables can be ascertained only through a longitudinal study of either a cohort or a case-referent design.

A clearer understanding of the interrelationship of suicidal thoughts with other types of morbid ideation has implications for both screening and clinical practice. Although a thought of suicide is strongly associated with a suicide attempt, the addition of thoughts of death, particularly a desire to be dead, potentiates the impact of a thought of suicide. This magnified risk may be due to the prolonged duration of the other two types of ideation. Self-destructive, morbid thoughts over an extended period of time provide clear indications for intervention activities. Because duration of ideation appears to enhance risk, we suggest that in the assessment of suicidal potential among substance-abusing adolescents one should elicit not just the presence of suicidal thoughts but their duration and tenacity.

A history of victimization significantly increased the risk of a suicide attempt only for males. The consistency of this finding across all indicators of victimization suggests that this may not be a chance result. Although it is possible that females can sustain victimization with less adverse emotional effects than males, we are not aware of any empirical findings suggesting such a trend. Rather, our finding could indicate that females were at very high risk for suicide attempts for reasons apart from victimization. In such a situation, victimization would not confer any observable added risk. Data supporting such an explanation are seen in Table 3, where for each level of suicidal ideation, the risk of attempted suicide is greater for females than for males. Furthermore, females were two and a half times more likely than males to have met criteria for major depressive disorder. Because of the excess of these risk factors among females it is possible that the deleterious impact of victimization is masked in this population of adolescent girls.

Lastly, the finding that removal from the home only slightly increases the probability of attempted suicide for maltreated subjects prompts three possible explanations. The first is that *severity* of victimization does not influ-

ence adverse emotional states associated with suicidal behavior. This explanation is not supported by the present data, and it is an unlikely explanation because studies have shown that children who have been severely abused have more deleterious outcomes than children who have experienced only mild abuse. A second explanation may be that removal from the home is not a good marker of severity of victimization. However, since the placement of a child outside the parental home is traumatic, is difficult to arrange, and involves the use of limited resources, protective authorities do not consider such action except in extreme cases of maltreatment. A third explanation for the slight increment in risk is that removal from the home is both a marker of severe victimization and, at the same time, potentially a restorative event. Children who have been removed from their homes may well have suffered more extreme abuse than those who were not removed, but they may also have had the advantage of a healing environment not available to children who experienced less severe victimization but who remained in their homes.

The results of this study indicate that youths who meet criteria for dependence on alcohol or drugs appear to be at exceptionally high risk of attempted suicide. Since a history of attempted suicide is known to be the most powerful predictor both of subsequent attempts and of completed suicide,[25,26] special vigilance is justified for substance-dependent adolescents, especially if a suicidal thought occurs in individuals who also have other morbid thoughts of long duration. The finding that morbid thoughts of extended duration combined with a thought of suicide magnify the risk of attempted suicide has not previously been quantified. Although this finding may apply only to adolescents at the most extreme end of substance abuse, further research is warranted among both adolescents who are substance abusers but not chemically dependent and adolescents who are not substance users. Similar findings in diverse populations of adolescents may suggest opportunities for more accurate community-based screening and suicide prevention efforts. □

Acknowledgments

This study was partly supported by a grant from the National Institute of Drug Abuse (RO1-DA-05834-02), by a grant from the William T. Grant Foundation (86-1079-86), and by support from the American Suicide Foundation.

The Sexual Assault of Women at Work in Washington State, 1980 to 1989

Bruce H. Alexander, MS, Gary M. Franklin, MD, MPH, and Marsha E. Wolf, PhD

A B S T R A C T

Sexual assault in the workplace and the related factors have not been well studied. Workers' compensation claims data were used to describe work-related sexual assaults in Washington State between 1980 and 1989. Sixty-three cases of work-related rape were identified during this study period. The occupations of the rape victims were similar to occupations identified as high risk for other intentional injuries, and the rape incidents were characterized by isolation from the public and from coworkers. Estimates of industry-specific rates are presented. The identification, evaluation, and prevention of sexual assault and other workplace violence are discussed. (*Am J Public Health.* 1994;84:640–642)

Introduction

Work-related injuries from violence are recognized as an important workplace safety issue.[1,2] Approximately 12% of all occupational fatalities are homicides,[2,3] accounting for 40% of such fatalities among women and 10% among men.[4–6] Circumstances surrounding the occurrence of rape in the workplace and the characteristics of the victims are not well known, although some occupations may involve high risk.[7] Such information is important in order to develop and implement appropriate prevention strategies. We used workers' compensation claim data to describe rapes occurring in the workplace in Washington State from 1980 to 1989.

Methods

The Department of Labor and Industries is the sole regulator of workers' compensation coverage in Washington State. The state fund covers approximately two thirds of all nonfederal workers in Washington State; it excludes those working for self-insured establishments and workers covered by federal programs. The workers' compensation database contains diagnostic information (*International Classification of Diseases,* ninth revision,[8] codes and Z16.2 nature of injury codes[9]), medical procedure billing information, and limited information describing the injured worker, the type of establishment, and the occurrence of the injury. A more detailed description of this administrative database can be found elsewhere.[10]

Claims filed for work-related rape from 1980 to 1989 were identified by the Z16.2 nature of injury code for rape (Z16.2 code 600). Microfiche of claim records for these individuals were reviewed to validate three inclusion criteria: the occurrence of a rape, whether the claim was accepted as a work-related injury, and whether the establishment was covered by the state fund. Characteristics of the rape victims, types of establishments, and circumstances surrounding the incident were also recorded.

Employee hours worked at establishments covered by the state fund were obtained to estimate industry-specific rates. Age- and gender-specific proportions for each industry were determined from 1980 US census data for Washington State[11] for all persons over the age of 15 for whom a usual occupation was listed. Industry-specific rates of rape were calculated as rapes per 100 000 full-time equivalent female workers (2000 hours = 1 full-time equivalent female worker for 1 year).

Results

Eighty-one claims of women raped in the workplace during the study period were initially identified. Upon review, 18 claims filed were excluded, 7 because

TABLE 1—Age Distribution of Women Reporting Workplace Rape and Women Reporting an Occupation in the 1980 US Census of Washington State

Age, y	Rape Victims No.	Rape Victims %	Census, %[a]
<20	13	20.6	10.1
20–29	33	52.4	31.9
30–39	12	19.0	23.0
40–49	3	4.8	14.2
50+	2	3.2	20.7

[a]15 years of age and older.

they were not accepted by the Department of Labor and Industries as being work related, 3 because they involved other work-related injuries misclassified as rapes, and 8 because they involved businesses not covered by the state fund. The remaining 63 rapes were included in this analysis.

The rape victims tended to be younger than the population of women reporting a usual occupation (Table 1). More than half of the reported rapes occurred between the hours of 7 PM and 6 AM (Table 2). Fifty-three (85%) of the women were working alone when the rape occurred, a proportion that increased during the daytime hours. Fifty-four (86%) of the assailants were strangers, seven (11%) were coworkers, and two (3%) were patients in the institution at which the rape occurred. Robbery was a concurrent motive in 30% of the incidents, but in a smaller proportion during the day.

Twenty-two occupational groups were identified from the original claim forms (Table 3). Of note, five of the six food service workers were employed at fast food establishments, and four of the five bartenders worked in taverns. Two or more rapes were reported in 12 industries (Table 4), and one rape occurred in each of an additional 16 industries. The annual rate of work-related rape for all industries was 1.5 per 100 000 full-time equivalent female workers. The rate for industries reporting a rape was 4.4 per 100 000 full-time equivalent female workers. Taxi drivers had the highest rate of work-related rape, followed by job training and related services and veterinary services.

TABLE 2—Circumstances of Work-Related Rape Incidents Identified through Washington State Workers' Compensation Claims Data: 1980 to 1989

Discussion

The problem of intentional injuries in the workplace, especially nonfatal injuries, lacks a clear description. This dearth of information is, in large part, due to problems in identifying work-related assaults, particularly sexual assaults. Workers' compensation claims identify assaults only if they result in lost workdays or require medical treatment. Furthermore, only 16%[12] to 53%[13] of rapes are reported to authorities. Consequently, our study may substantially underestimate the incidence of work-related rape in this population. Nonetheless, some aspects of work-related rapes identified in this study are notable in their similarity to other reports of workplace violence and suggest that rapes occurring in the workplace are not random events.

This study identified occupations previously reported as involving high risk for rape in the workplace (convenience store clerks, property management personnel, and motel housekeepers)[7] and several additional occupations reporting more than one rape. These groups are comparable to occupational groups reported to have a greater risk of work-related homicide.[4–6,14]

Isolation of workers from fellow employees and the public appears to increase the risk of work-related rape. The rapes in this study frequently occurred between late evening and early morning. No data are available on the distribution of women working during these hours, yet the rapes occurred disproportionately during traditional nonworking hours. Furthermore, a large proportion of the rapes (85%) befell victims working alone at the time of the incident.

The calculated rates were unstable as a result of small numbers, and particular characteristics of the workplace environment cannot be linked to broad three-digit Standard Industrial Classification categories. Of interest, however, the rate for taxi drivers, an industry characterized by workers working in very isolated circumstances, was much higher than those for the other industrial groups.

TABLE 3—Occupations Reporting One or More Rapes between 1980 and 1989 in Washington State

Occupation[a]	Reported Rapes No. (n = 63)	%
Convenience store clerk	6	9.5
Food service	6	9.5
Retail sales	5	7.9
Nursing home and patient care	5	7.9
Bartender	5	7.9

[a]2000 worker hours per year.
[b]Rate of rapes per 100 000 full-time equivalent female workers employed by establishments covered by the Washington State fund.
[c]Includes job placement and counseling.

Intentional injury, including sexual assault in the workplace, is clearly an occupational safety problem. For more than a decade, public health researchers have recognized that safety standards to prevent assault in the workplace are needed to meet the changing problems of workplace safety.[2,14] Interventions have been suggested to reduce the risk of assault by creating a workplace environment that would deter an assailant.[1] Potential deterrents to assault should be more thoroughly examined for all occupations that involve a high risk of intentional injury. Clearly, workplace violence is linked to broader social issues that cannot be addressed from the standpoint of workplace safety alone. Nevertheless, to meet the goal of a safe work environment for all workers, the issue of violence in the workplace must be addressed. □

Acknowledgments

This research was supported by Harborview Injury Prevention and Research Center grant CCR 49-002570, Centers for Disease Control, and by the Accident and Medical Aid Funds of the State of Washington, Department of Labor and Industries. These research funds are targeted to reducing the incidence of and disability related to occupational injuries and illnesses. Bruce H. Alexander was supported by a training grant in environmental epidemiology and biostatistics from the National Institute for Environmental Health Sciences (T32ES07262).

This work was presented at the 121st Annual Meeting of the American Public Health Association, October 24–28, 1993, San Francisco, Calif (Session 3050, Abstract P.281).

We thank Drs Frederick P. Rivara and Peter Cummings for their review of and thoughtful comments on this manuscript.

Preventing Occupational Illness and Injury: Nurse Practitioners as Primary Care Providers

Jane Lipscomb, RN, PhD, Barbara Burgel, RN, MS, Laura Wotowic McGill, RN, MS, and Paul Blanc, MD, MSPH

A B S T R A C T

Nurse practitioners with master's degrees were surveyed to assess the type and volume of occupational health services provided by primary care as compared with occupational health practitioners and the knowledge base in occupational health in these two groups. Thirty-six percent of 224 nonoccupational health nurse practitioners reported caseloads with 10% or more occupationally related chief complaints; 21% reported treating work-related injury or illness at least once per week. By contrast, a large percentage of nonoccupational health practitioners failed the knowledge-based exam. Large-scale prevention of occupational illness and injury warrants that primary care providers receive training in occupational health. (*Am J Public Health.* 1994;84: 643–645)

Introduction

Responsibility for most occupational health management falls to nonoccupational specialists.[1] The potential preventive impact of primary care health providers on this public health problem could be dramatic.[2] Nurse practitioners are an integral part of primary health care services in many practice settings. In contrast to primary care physician training, in which the need for occupational health education has received considerable attention, the lack of such training in nursing programs has been largely overlooked, and the amount of occupational health services provided by nurse practitioners has not been systematically evaluated.[1-7] To better understand the role of nurse practitioners in the recognition and prevention of occupational illness and injury, we surveyed occupational health services provided by primary care nurse practitioners and assessed their recognition of occupational illnesses and case management.

Methods

Study Site

We studied graduates of a large, university-based school of nursing that has offered graduate education in occupational health nursing since 1978, one of only seven master's-level programs in the country providing such specialized training. The occupational health nurse practitioner specialization is one of five 2-year nurse practitioner master's tracks within this school of nursing. The four others are adult, gerontology, family, and women's health. The occupational health nurse practitioner program includes a minimum of 14 academic quarter credits of didactic occupational health course work, other didactic community health nursing and primary care course work, and 540 practicum hours in primary care and occupational health settings. The adult nurse practitioner track (one of four nonoccupational health programs we surveyed) is closely affiliated with the occupational health nurse practitioner program, with students enrolled in a similar primary care curriculum but not required to engage in any occupational health specialty course work. In contrast, the gerontology nurse practitioner track shares only some of the primary care course work with the occupational health nurse practitioners and adult nurse practitioners, and students have less contact with the occupational health curriculum than the adult nurse practitioner students. Finally, the family health and women's health nurse practitioner tracks have separate curricula that do not overlap courses with the occupational health nurse practitioners.

Survey Methods

We surveyed the 509 nurse practitioner master's graduates for the years 1978 through 1989. The survey instrument covered current and past employment, the type and volume of occupational health services rendered in the past 6 months (including occupational health illness management, treatment of injuries, and health surveillance), and a knowledge assessment based on 10 multiple-choice clinical case scenarios. The text of the questionnaire is available upon request.

Statistical Analysis

We first compared proportions among occupational respondents and respondents from all other programs by

TABLE 1—Nurse Practitioners' Provision of Occupational Services, by Training Program of Graduates

Occupational Service	Nurse Practitioner Program: Occupational (n = 31), %	Nurse Practitioner Program: Nonoccupational (n = 223), %
Routine occupational history taking*	68	35
Frequent work-related chief complaints*	87	36
"Doctor's first report" completion*	81	32
Treatment of work injuries*	65	21
Treatment of illnesses	35	21
Provision of surveillance*	65	17

Note. Positive responses were defined as follows: occupational history taking among one third or more of clients, occupational chief complaint among 10% or more of clients, doctor's first report of occupational illness and injury ever filed on any client (legally required reporting procedure in California), and treatment of work injuries or illness and provision of surveillance once or more per week.
*$P < .001$ (occupational as compared with nonoccupational program graduates).

TABLE 2—Nurse Practitioners' Responses to 10 Clinical Case Scenarios on Occupational Health Test

Case Scenario Type	Occupational Program Graduates' No. of Correct Responses, Mean ± SD	Nonoccupational Program Graduates' No. of Correct Responses, Mean ± SD
Occupational disease identification*	3.9 ± 1.0	2.2 ± 1.2
Occupational case management*	4.1 ± 1.2	3.4 ± 1.5
Both case scenario types*	8.0 ± 1.7	5.6 ± 2.4

Note. Five clinical case scenarios were included in each category.
*$P < .05$ (occupational as compared with nonoccupational program graduates).

means of chi-square tests. We calculated Cronbach's alpha to evaluate the consistency of responses to the 10 case scenario questions. We compared the mean frequencies of correct responses by student's *t* test. A priori, we defined a "passing score" as 70% correct. We used logistic regression analysis to estimate the association between past training program and passing score, taking into account the effect of postgraduate occupational field experience in practice. The CRUNCH[8] and Epistat[9] statistical packages were used in conducting analyses.

Results

Of 509 questionnaires mailed, 23 (5%) were returned as nondeliverable. Three hundred thirty-seven questionnaires were completed, for an overall response rate of 69% of those deliverable. We excluded from further analysis 64 respondents not currently working in any clinical setting. We also excluded 18 additional respondents from the four nonoccupational health programs who were working in an occupational health rather than primary care setting. In total, we analyzed data from 254 respondents.

Of 31 occupational health program respondents, 22 (71%) were working in an occupational health setting (e.g., on-site occupational health service, occupational health specialty clinic). Four others were designated occupational health specialists in another clinical setting. Among 223 nonoccupational nurse practitioner program graduates, the breakdown by program was as follows: adult, 57 (26%); gerontology, 31 (14%); family, 74 (33%); and women's health, 61 (27%). Only 27 (12%) of the 223 nonoccupational respondents worked in inpatient settings. The remainder worked in the following settings: outpatient clinic of an inpatient center (n = 58), health maintenance organization (n = 51), private practice (n = 38), community clinic (n = 22), or "other" (n = 27).

Table 1 presents data for occupational health activities among occupational nurse practitioner program graduates as compared with all others. Occupational injury management included any of four specific services, illness management involved any of five services, and surveillance activities included any of seven specific activities. A greater proportion of occupational health graduates provided each type of occupational service; nonetheless, such activities were not infrequent for the nonoccupationally trained. For example, 21% of nonoccupational health graduate survey respondents reported providing at least one type of injury or illness management once or more per week. The most common specific services were for work-related stress, work-related back injury/chronic pain, work-related muscular strains other than back injury, and preplacement exams. Indeed, for occupational stress, the percentage of nonoccupational health nurse practitioners providing evaluations and/or treatment was higher than that among occupational health nurse practitioners (18% vs 13%). When defined by the less frequent criterion of treatment once per month rather than once per week, 50% among the nonoccupationally trained reported treating work-related musculoskeletal problems, and 20% reported treating work-related asthma. As shown in Table 1, 81 (36%) nonoccupational graduates reported 10% or more of their caseload as involving potentially occupationally related chief complaints. For this group, the overall mean frequency of occupationally related chief complaints was 9%.

We evaluated responses to the 10 case scenarios to assess the reliability of these questions in assessing a respondent's ability to correctly identify occupational illnesses and intervention. The Cronbach's alpha coefficient for the 10 cases was .73. The scenario test results for occupational health and nonoccupational health nurse practitioner graduates are presented in Table 2. Graduates of the occupational health program correctly identified a mean of 3.9 illness cases, in comparison with 2.2 by graduates of the nonoccupational health programs ($P < .001$). Of the 5 cases assessing intervention strategies, occupational health graduates correctly identified a mean of 4.1 interventions, as compared with 3.4 for nonoccupational health

graduates ($P < .012$). Defining a priori 70% as a passing test score, 13% of occupational health graduates failed, as compared with 60% of nonoccupational health graduates ($P < .05$). Taking into account year of training, frequency of occupational history taking, treatment of work-related chief complaints, and filing of "doctor's first reports," graduation from the occupational practitioner program study was the only factor significantly associated with a passing test score (odds ratio [OR] = 1.4, 95% confidence interval [CI] = 1.1, 1.7).

Discussion

Our study hypothesis was that nurse practitioners in primary care settings provide frequent occupational health services without the formal training to facilitate the prevention, diagnosis, and treatment of work-related illnesses and injuries. These survey data strongly support this hypothesis. Twenty percent of nonoccupational health graduates treated occupational injury and occupational illness at least weekly. Since we included gerontology and women's health specialty nurse practitioners, who are less likely to provide occupational health services, ours would be a conservative estimate of the types and frequency of services likely to be provided by general primary care nurse practitioners who see higher rates of patients in the labor force.

Despite these frequent primary occupational care responsibilities, only 4 in 10 nonoccupational health specialists achieved a passing score on a knowledge-based examination testing both diagnosis and case management in occupational health. The test appeared to have good internal and external validity.

Our findings are consistent with those from other studies of the potential importance of occupational health in primary care. In one study, 16% of patients of an outpatient practice with a predominantly "blue-collar" population reported that their health problem was related to work.[10] In another survey, 55 physicians in general practice reported that, on average, 3.5 patients per week had a work-related condition.[11] Assuming treatment of as many as 16 patients per day, this would approximate 4% of patients seen. Our findings of nonoccupational nurse practitioners reporting that 9% of their clients present with a potentially work-related chief complaint falls between that of patient self-reports and physician reports in these two published studies.

Our findings suggest that primary care nurse practitioners are on the "front line" for identifying and potentially preventing occupational illnesses and injuries. At the same time, this survey indicates that these health care providers are not provided the optimal training to identify, treat, or prevent this morbidity; they may be in the trenches, but they have not been supplied with enough ammunition. We believe that if primary care practitioners, including nurse practitioners, have the responsibility for diagnosing and managing occupational health problems, health care policymakers and educators have the duty to guarantee the training and resources needed to fulfill their duty. □

Occupational Injury Deaths of 16- and 17-Year-Olds in the United States

Dawn N. Castillo, MPH, Deborah D. Landen, MD, MPH, and Larry A. Layne, MA

ABSTRACT

Data from the National Traumatic Occupational Fatalities surveillance system were used to analyze occupational injury deaths of civilian 16- and 17-year-olds during 1980 through 1989. There were 670 deaths; the rate was 5.11 per 100 000 full-time equivalent workers. The leading causes of death were incidents involving motor vehicles and machines, electrocution, and homicide. Workers 16 and 17 years old appear to be at greater risk than adults for occupational death by electrocution, suffocation, drowning, poisoning, and natural and environmental factors. Improved enforcement of and compliance with federal child labor laws, evaluation of the appropriateness of currently permitted activities, and education are encouraged. (*Am J Public Health.* 1994;84:646-649)

Introduction

Although several studies have examined nonfatal occupational injuries among youth,[1-8] only one published study has investigated occupational injury deaths of young people across the United States. Suruda and Halperin analyzed data from Occupational Safety and Health Administration (OSHA) fatality investigations between 1984 and 1987.[9] Of the 104 deaths investigated, 30% involved industrial vehicles and equipment, 17% were electrocutions, and 11% resulted from falls. Thirteen percent of the fatally injured youth were 15 years of age or younger.

Analysis of OSHA fatality investigations does not present a complete picture of occupational injury death in the United States, however. OSHA investigates only about 25% of work-related deaths, most of which are concentrated in the construction and manufacturing industries.[9] OSHA does not investigate homicides, most transportation incidents, and industries regulated by other federal agencies such as the Mine Safety and Health Administration and the Department of Transportation.

To obtain a more comprehensive picture of occupational injury deaths among youth, we analyzed data from the National Traumatic Occupational Fatalities surveillance system. This surveillance system is not limited by the industry or occupation in which the death occurred and includes all causes of occupational injury death. Because the minimum age included in the system is 16 years, the analysis was limited to 16- and 17-year-olds.

Methods

Data from the National Traumatic Occupational Fatalities surveillance system were used to analyze occupational injury deaths of 16- and 17-year-olds—and, for comparison, adults 18 years of age and older—for the years 1980 through 1989 (the most recent years for which data are available). This ongoing surveillance system, maintained by the National Institute for Occupational Safety and Health, includes information from death certificates for all work-related injury deaths reported by the 52 vital statistics reporting units in the United States (the 50 states, New York City, and the District of Columbia). To be included in the system, death certificates must meet the following criteria: the victim was at least 16 years of age; the death was attributed to an external cause (i.e., injury or poisoning), as designated by the *International Classification of Diseases*, ninth revision (ICD-9)[10]; and the certifier responded positively to the "injury at work" item on the death certificate. Information from the immediate, contributory, and underlying cause of death and injury description fields on the death certificate was used to code the external causes of death (ICD-9 codes E800 through E999). The industry division was coded from the "usual industry" field on the death certificate according to the *Standard Industrial Classification Manual, 1987*.[11]

For calculation of rates, data on hours worked were obtained from the Bureau of Labor Statistics' Current Population Survey, a monthly survey of US households selected from a probability sample representative of the civilian noninstitutional population.[12] For each age group, average hours worked were converted to full-time equivalent workers by multiplying the average number of hours worked per week by 52 weeks per year and dividing by 2000 (the average number of hours worked per year).

Note. ND = not determined because of instability of rates based on small numbers.
[a]Rate per 100 000 full-time equivalents (FTE). The employment figures used in calculation of rates for 16- and 17-year-olds were 7 270 705 male FTE, 5 837 621 female FTE, and 13 103 732 total FTE. The employment figure for adults was 1 000 000 000 FTE.
[b]16- and 17-year old occupational injury death rate/adult rate.

Rates of occupational injury death were calculated per 100 000 full-time equivalent workers.

Results

There were 673 occupational injury deaths to 16- and 17-year-olds for the 10-year period from 1980 through 1989. Military personnel accounted for 3 of these deaths (young people 17 years of age may enter the military with permission from their parents). These military cases were removed from further analysis because comparable employment data for military personnel were not available. The average annual rate of occupational injury death for 16- and 17-year-olds was 5.11 per 100 000 full-time equivalent workers; the rate for adults 18 years of age and older was 6.09 per 100 000.

Two hundred ninety-seven (44%) of the deaths occurred during the summer months (June through August). There were 143 deaths (21%) during September through November and approximately 100 deaths each during the winter and spring months.

There were 429 deaths involving 17-year-olds and 241 deaths involving 16-year-olds; 617 of the victims were male. Most of the victims (540) were White; 62 were Hispanic, 53 were Black, and 15 were of other or unknown race/ethnicity.

The rates of occupational injury death of 16- and 17-year-olds dropped from 7.16 per 100 000 full-time equivalent workers in 1982 to 3.94 per 100 000 in 1983 and have been stable since. The rate in 1989 was 3.67 per 100 000 full-time equivalent workers.

Occupation and industry information was not available for most cases. The "usual occupation" for 388 (58%) of the fatally injured youth was reported to be "student." Table 1 provides the frequency of deaths by industry division. Because industry was available for only 354 (53%) of the fatally injured youth, the interpretation of these data should be restricted to identifying the minimum number of deaths within each division.

The distribution of occupational injury deaths by cause and rates for each cause are presented in Table 2 for 16- and 17-year-olds and, for comparison, adults 18 years of age and older. The leading causes of occupational injury death for both age groups were incidents involving motor vehicles and machines. Although the overall risk of occupational injury death is lower for 16- and 17-year-olds than for adults, the risk for occupational injury death by electrocution, suffocation, drowning, poisoning, and natural and environmental causes appears to greater for young people than for adults (14 of the 17 youths who died from natural and environmental causes were struck by lightning).

Motor vehicles accounted for nearly 25% of the occupational injury deaths of 16- and 17-year-olds. Thirty-three percent (53) of the fatally injured youth were driving a motor vehicle, 17% (28) were passengers, and 20% (32) were pedestrians. Information included on the death certificate was insufficient to determine whether the fatally injured youth was a driver, passenger, or pedestrian in 28% (46) of the deaths involving motor vehicles.

Agricultural machinery accounted for 68% of the machine-related deaths; tractors accounted for 44% of the machine-related deaths. Of the 50 tractor-related deaths, at least 29 were caused by rollovers, and 4 were a result of the individual's being run over; power takeoffs contributed to at least 3 of the deaths.

Events leading to electrocution could not be determined for nearly 30% of the electrocutions. Contact with an energized power line was the most frequent cause, accounting for 55% (44) of electrocutions.

Discussion

Although the National Traumatic Occupational Fatalities surveillance system is the best available source of information on occupational fatalities in the United States for the period of this study, it has limitations. Identification of work-related injury deaths and appropriateness of occupation and industry information on the death certificate are the primary issues. In a review of 10 studies that used multiple sources to identify the universe of fatal work-related injuries, Stout and Bell reported that, on average, death certificates captured 81% of work-related injury deaths.[13] Thus, frequencies and rates presented in this paper should be considered conservative estimates. Studies have demonstrated agreement of 60% to 76% between "usual industry" and "usual occupation" entries on the death certificate and employment at the time of death.[14] On the basis of the high percentage of young people whose occupation was listed as "student" in this analysis, the correspondence appears to be poorer for youth. Jenkins et al. provide a thorough discussion of the methodology and limitations of the National Traumatic Occupational Fatalities surveillance system.[15]

Although occupational injury deaths declined in the early part of the decade, exposure to hazardous work environments remains a problem. The primary law designed to protect young people from adverse effects of employment is the Fair Labor Standards Act of 1938. The act sets minimum age standards for employment, limits hours and occupations in which 14- and 15-year-olds may work, defines occupations and tasks that are hazardous, and proscribes hazardous work for nonagricultural workers under 18 years of age[16] and agricultural workers under 16 years of age.[17] There are numerous exemptions to the act, the most notable being that children may work on the family farm at any age, at any time, and in any occupation, including work declared to be hazardous. In addition to the protection provided by federal law, all but four states—Colorado, Kansas, Maryland, and Mississippi—have child labor laws.[18]

The lack of detailed information available from death certificates precluded the enumeration of deaths in the National Traumatic Occupational Fatalities system resulting from activities permitted and not permitted under the Fair Labor Standards Act. Motor vehicle driving, which resulted in the deaths of at least 53 young people, is prohibited for nonagricultural workers under 18 years of age. Suruda and Halperin reported that 41% of occupational injury deaths of youth investigated by OSHA occurred while the child was engaged in work prohibited by federal child labor laws.[9] The small number of child labor inspectors and inadequate penalties have been cited as reasons for the persistence of child labor violations.[6,18] Increased coordination between OSHA and federal and state labor departments[9,19] and increased penalties sufficient to deter violations have been recommended as ways to improve enforcement and compliance with child labor laws.[19]

At least 110 of the fatally injured youth worked in the agriculture, forestry, and fishing industry. The Fair Labor Standards Act declares that operation of several types of agricultural machines, including tractors of more than 20-power-takeoff horsepower, is hazardous for those younger than 16 years of age. The appropriateness of hazardous agricultural work for young people deserves evaluation. Legislation recently enacted in Virginia that raised the minimum age from 16 to 18 for several hazardous agricultural occupations[20] should be evaluated. Formal training in the safe operation of farm equipment and the installation of protective devices, such as rollover protective structures, may also reduce the incidence of injury to children.

The appropriateness of youth employment in the construction industry should also be evaluated. The construction industry has the second highest rate of occupational injury death among workers of all ages[15] and contributed to the deaths of at least 59 young people.

In addition to regulation and enforcement, there is a role for education in preventing occupational injury of youth.[6] Young people, parents, teachers and school boards, physicians, and the business community must be educated about child labor laws and the risks of injury in the workplace. Youth and their parents require this information to make informed decisions about appropriate jobs for young people. Teachers, school boards, and physicians should consider these issues when dispensing work permits. The business community needs to be aware of its responsibilities under the law to protect youth in its employ and to understand the potential for tragedy related to noncompliance with existing laws.

This study of death certificate data has identified the leading causes of occupational injury death of 16- and 17-year-olds and examined differences in risk between youth and adults by external cause of death. Additional research is needed to understand the circumstances under which young people die from injuries incurred while working and to identify ways in which such deaths can be prevented. Epidemiologic data addressing the effect of training, job experience, supervision, job stressors, work permits, and child labor laws on the risk for occupational injury death of youth are needed. □

Head Injuries Incurred by Children and Young Adults during Informal Recreation

Susan P. Baker, MPH, Carolyn Fowler, PhD, Guohua Li, MD, DrPH, Margaret Warner, BS, and Andrew L. Dannenberg, MD, MPH

ABSTRACT

To examine injuries related to playground equipment, children's vehicles, roller skates, and skateboards, 1991 data on emergency room patients younger than 25 years in the Consumer Product Safety Commission's 91 surveillance hospitals were used. Head injury was the primary diagnosis for an estimated 58 480 patients, exceeding the total number of head injuries to bicyclists younger than 25 years. The head injury rate decreased with age. The large number and high rate of head injuries in children involved in a variety of recreational activities suggests the value of multipurpose helmets. (*Am J Public Health*. 1994;84:649–652)

Introduction

Sports and recreation account for more than 40% of all head injuries in children and adolescents, exclusive of those related to motor vehicles.[1] This study was undertaken to estimate the number of hospital-treated head injuries in children and young adults that occur in association with a variety of informal recreational activities. The activities studied involved playground equipment, children's vehicles, skateboards, and roller skates. Children's vehicles included tricycles, wagons, scooters, and wheeled riding toys.

The use of helmets, although increasing among bicyclists, is rare in other informal recreation. Of special interest was the possible value of multipurpose helmets that could be used in several activities.

Methods

The federal Consumer Product Safety Commission (CPSC) conducts active surveillance of injured patients treated at 91 hospital emergency rooms chosen to be nationally representative; this constitutes the National Electronic Injury Surveillance System. To develop national estimates, cases are weighted on the basis of the sampling fraction.[2] For activities in the present study, the average case sampled represented 53 patients.

For each activity listed in Table 1, CPSC provided a series of detailed tabulations for patients treated in 1991, including age by primary anatomic site of injury, nature of injury, sex, and disposition. Data on place of injury, missing for 37% of the patients, were not used in the analyses. Data on the other variables were complete for all patients. Head injuries were defined to include scalp lacerations, skull fractures, concussions, and other brain injuries; injuries to the face, mouth, eye, or ear were excluded.

Chi-square tests were used to assess age differences in the percentage of head injuries and differences in hospitalization rates between emergency room patients with head injuries and those without head injuries. For chi-square calculations, the actual number of patients in the sample was used rather than the estimated number in the general population.

For comparison with injuries incurred during these recreational activities, we analyzed injuries to bicyclists during 1991, using computerized data provided by CPSC.

Results

An estimated 464 000 persons younger than 25 years received emergency

FIGURE 1—Head injuries as a percentage of all injuries incurred during informal recreation, by age and activity, 1991.

room treatment during 1991 for injuries related to playground equipment, children's vehicles, skateboards, and roller skates. Motor vehicles were involved in 4% of all injuries related to children's vehicles and 1% of injuries related to skateboards and roller skates. The greatest difference between males and females was for skateboarding, with more than six times as many injuries in males as in females. Females received more roller skating injuries (1.4:1). For other activities, the male:female ratio ranged from 1:1 to 1.9:1.

Head Injuries

For an estimated 58 480 patients, 13% of the total, the head was the primary site of injury. Head injuries constituted 15% of all injuries associated with playground equipment, 20% of injuries from children's vehicles, and 6% of injuries from skateboards and roller skates. The proportion of injuries that involved the head decreased with age for each major category of activity; all were statistically significant at $P < .01$ (Figure 1). For informal recreational activities as a whole, head injuries constituted 21% of injuries to children younger than 5 years, 11% of injuries to children aged 5 through 14 years, and 5% of injuries to persons aged 15 through 24 years. Head injuries to bicyclists showed a similar pattern, decreasing with age as a proportion of all injuries.

For all ages combined, three fourths (74%) of the head injuries occurred in connection with playground equipment (Table 1). Swings, slides, and monkey bars were involved in 65% of head injuries from recreational activities for children younger than 5 years and 60% of those for children aged 5 through 14 years. Skateboarding and roller skating accounted for 62% of the head injuries from these activities for persons aged 15 through 24 years. The actual number of skateboard- and roller skate–related head injuries for persons aged 15 through 24 years was less than one fifth the number for the age group 5 through 14 years.

Children aged 5 through 14 years incurred 60% of all head injuries from activities involving playground equipment and 77% of head injuries involving skateboards and roller skates. Children younger than 5 years sustained 72% of the head injuries related to children's vehicles.

The total number of head injuries from the recreational activities studied (58 480) was even higher than the number of head injuries from bicycling (55 998) in the same age range. Head injuries from the recreational activities were more than twice as frequent as bicyclists' head injuries for children younger than 5 years and were 80% as frequent as head injuries from bicycling among children aged 5 through 14 years.

The head injury rate per 100 000 population for the selected activities was

highest for the age group 1 through 4 years. For bicycling, the head injury rate was highest for children aged 5 through 14 years (Figure 2).

Hospital admission was more than twice as common among patients with head injuries as among those without (5.7% vs 2.5%, $P < .001$) (Table 2). Head injuries associated with skateboards had an especially high proportion of admissions to hospitals (12.7%). Among bicyclists, 8.5% of those with head injuries were admitted, vs 1.7% of those without ($P < .001$).

Discussion

More than 58 000 head injuries occur annually in children and young adults in association with playground equipment, children's vehicles, skateboards, and roller skates. The percentage of injuries that involve the head is highest in children younger than 5 years, probably owing in part to the fact that the head is larger in proportion to the rest of the body in very young children. In addition, injury rates are highest in the youngest children. These facts, as well as the consequences of head injury, point to the need to take special precautions against head injury in children.

CPSC injury data are useful for providing national estimates but are limited by a lack of detail on injury severity; hospital admission is the only reliable severity indicator. Almost 6% of the head injuries studied resulted in hospital admission. In addition, some mild head injuries, including ones not resulting in hospital admission, have potentially severe long-term sequelae.[3]

Estimates of head injuries based on emergency room data are conservative because they exclude injured children who are treated outside hospitals or who do not seek medical attention. Such children may be less likely to have head injuries than those seen in emergency rooms, but data are lacking to clarify this point.

Population-based data on informal recreation are limited by the lack of exposure or denominator information that would identify recreational activities with a high risk of injury per unit of participation.[4] In contrast, for bicycling, one can use data from the Nationwide Personal Transportation Survey to calculate injury rates per million trips.[5] Even when high-risk activities cannot be singled out, however, the absolute number of injuries may suggest the need for environmental modifications[6] or protective headgear—for example, in the case of the use of swings, which were associated with 30% of all the head injuries.

Bicycle helmets have been shown to be effective in reducing head injuries[7,8] and are rapidly gaining in popularity. Because head injuries from other informal recreational activities are almost as common as head injuries in bicyclists aged 5 through 14 years and far more common in younger children, the poten-

tial value of helmets for activities other than bicycling deserves emphasis.

Helmets are appropriate for a variety of activities at all ages, but are especially appropriate for children because of their high rates of head injury. Some children may participate in many recreational activities yet spend little time engaged in any single sport. Even when specialized helmets exist for a sport, a parent may not wish to invest in a single-purpose helmet for a child who is trying out an activity for the first time—yet inexperienced children are often at increased risk of injury.[9,10]

Multipurpose helmets are an appealing approach to the problem of head injury in informal recreational activities that lack specifically designed helmets. Rivara has urged the active promotion of helmets that can be used by children and adolescents in many sports.[1] Wilson et al. have pointed to the advantages of "a lightweight, inexpensive helmet that would be attractive to children and protective during a number of different recreational activities."[11]

Sports in which high-velocity impacts are common, such as skateboarding and in-line skating, may require helmets that differ from those giving the best protection in falls from playground equipment. It seems probable, however, that a helmet for young children could give good protection in more than one kind of activity. A standard for multipurpose helmets is currently being developed by the Snell Memorial Foundation (Channing Ewing, MD, MPH, telephone conversation, June 29, 1993).

The injury prevention community should be proactive in the area of informal recreational activities, which otherwise may not be subjected to the degree of scrutiny applied to team sports and other organized recreation. Concern should extend both to traditional activities, such as use of swings and tricycles, and to new activities. Recently we identified a surge in head injuries related to in-line skates,[12] illustrating the need for prompt recognition of hazards associated with new products. In any recreational activity where head injury prevention is a concern, early emphasis on helmet use may be more effective than trying to make a later change in existing behavior. □

A Cost–Benefit Analysis of Legislation for Bicycle Safety Helmets in Israel

Gary M. Ginsberg, DrPH, MSc, and Don S. Silverberg, MD

ABSTRACT

Legislation requiring bicyclists to wear helmets in Israel will, over a helmet's 5-year duration (assuming 85% compliancy, 83.2% helmet efficiency for morbidity, and 70% helmet efficiency for mortality), save approximately 57 lives and result in approximately 2544 fewer hospitalizations; 13 355 and 26 634 fewer emergency room and ambulatory visits, respectively; and 832 and 115 fewer short-term and long-term rehabilitation cases, respectively. Total benefits ($60.7 million) from reductions in health service use ($44.2 million), work absences ($7.5 million), and mortality ($8.9 million) would exceed program costs ($20.1 million), resulting in a benefit–cost ratio of 3.01:1. (*Am J Public Health.* 1994;84:653–656)

Introduction

Almost all bicycle accident mortality results from head and brain damage,[1–5] and nonfatal head injuries sometimes result in victims requiring expensive, lifelong care for their disabilities.[6–11] Between 70.9% and 95.5% of head injuries and about 70% of fatalities involving head injuries could be prevented through the use of crash helmets.[12–21] Fewer than 2% of Israel's estimated 833 000 cyclists[22] currently use such helmets.[11,23]

During the period from 1967 to 1991,[24] accidents to bicyclists accounted for annual mortality, hospitalization,[23] and emergency room visitation rates of 5.02, 228.5, and 2262.4 per million, respectively,[24] after adjustment for the estimated 88.9% (95% confidence interval [CI] = 87.7%, 90.1%) underreporting of emergency room cases.[23,25] Hospitalization rates were stable throughout this period, while mortality rates decreased between 1975 and 1980 and then stabilized. Persons under 20 years old accounted for 57.0% of hospitalizations, and older individuals had higher case fatality rates[24] (Table 1).

This paper estimates the costs and benefits from expected reductions in mortality and morbidity if mandatory bicycle helmet use legislation were enacted in Israel.

Methods

Direct (i.e., including only health service benefits) and total (direct, work, and mortality) or societal benefit–cost ratios based on the parameters in Table 2 were calculated on a spreadsheet; a 5% per annum discount rate was used. Lifetime costs of premature mortality, institutional care, and special education were discounted and attributed to the year in which the accident occurred.

The 85% compliancy rate (see Table 2) is based on Israelis' 90% compliancy with car seat belt laws,[26] only 6% less than the 96% achieved for bicycle helmet use after legislation in Melbourne, Australia.[21]

The gross national product per capita method of valuing life,[27] which assigns an equal value to each member of society equivalent to the annual per-capita gross national product of the population ($10 728 in 1990), was used to estimate mortality costs. These costs were based on discounting the value of the deceased's expected years of life lost.

Results

In 1994, bicycle-related injuries will account for approximately 26.5 deaths, 1203 hospitalizations, and 11 913 persons requiring emergency room treatment.

The cost of crash helmets (current retail price: $23.40) for Israel's 833 000 cyclists would be $19.5 million. An additional $607 000 would be required over 5 years for health education purposes.

Legislation for bicycle helmet use in Israel would, over a helmet's 5-year duration,[28] prevent approximately 57 deaths. Also, it would result in 2544 fewer hospitalizations, 13 355 fewer emergency room visits, 26 634 fewer ambulatory visits, and 832 and 115 fewer short- and long-term rehabilitation cases (including 45 children needing special education), respectively (Table 3).

The direct benefit ($44.20 million) to cost ($20.14 million) ratio is 2.19:1. When benefits from reductions in work absences ($7.55 million) are included, the benefit–cost ratio rises to 2.57:1. After adding benefits from reductions in mortality ($8.94 million), the total benefit–cost ratio to society rises to 3.01:1 (Table 3).

Sensitivity analyses available upon request from the authors show the benefit–cost ratio to be sensitive to

(continued)

changes in the discount rate, duration of helmet life, compliancy rate, and helmet effectiveness and cost.

Direct benefit breakeven points (where direct benefits are equal to costs) are met if compliancy falls below 40%, helmets last only 25 months, the helmet effectiveness rate is 37.8%, helmets cost $52.29, or there are more than 4.15 riders per bike. Breakeven points to society are met if compliancy falls below 29.6%, helmets last only 18 months, the helmet effectiveness rate is 17.8%, helmets cost $72.08, or there are more than 5.68 riders per bike.

Changes in the percentage of emergency room visits, unemployment, head injury death, and bike ownership rates, as well as use of the human capital method to value life, had little effect on the benefit to cost ratios.

Discussion

If compulsory bicycle crash helmet legislation were enacted in Israel, considerable reductions in mortality, morbidity, and residual disablement would occur, resulting in net savings of $43.3 million to society over a 5-year period. In almost all of the sensitivity analysis scenarios, both direct and total benefits exceeded program costs.

The benefit–cost ratios are biased downward since our conservative model did not consider reduced pain, worry, grief, work losses for ambulatory visits, or even time off from housework as a result of bicycle injuries. Nor did we consider the intangible benefit of the lessening of anxiety concerning crashes by cyclists or by their friends and relatives. Our calculations excluded revenues from possible fines as a consequence of the legislation, since payments of fines represent simply transfer payments that result in neither a net gain nor a net loss to society.

Another conservative assumption was that helmets would not reduce severe facial injuries, since recent experience revealed a reduction in severe upper facial injuries of approximately 73% as a result of helmet use.[17] Including benefits from decreased upper facial injuries only slightly increased the direct and total benefit–cost ratios to 2.27:1 and 3.13:1, respectively.

Those who object to bicycle helmet legislation argue that legislation infringes on the freedom of the individual. However, there is a legal precedent created by the fact that already-estab-

lished legislation for motorcycle helmets in Israel has resulted in reduced morbidity and mortality.[24] Studies conducted in the United States have shown huge health service cost savings as a result of motorcycle crash helmet legislation.[29–34]

Health education campaigns alone (even with bicycle helmet subsidies) have achieved only low compliancy rates ranging from 7.2% to 32.2%.[14,21,35–39] However, when legislation was added to a health education campaign in Victoria, Australia, compliancy rates rose from 30% to 90% in under a year.[14,21] Similar legislation for children under 16 years of age in Howard County, Maryland, increased compliancy to 47% relative to 19% from a community education program alone in a neighboring county.[40]

The imposition of legislation, backed by the threat of fines, is a powerful and preferred means of raising helmet wearing compliancy. The monetary benefits are sufficiently large to warrant the government ministries and/or the major health insurance funds to consider subsidizing[41] the costs of providing helmets to Israeli bicyclists. □

TABLE 2—Parameters Used in Cost–Benefit Analysis (*Continued*)

	Parameter	Source
Emergency room *(continued)*		
Workdays lost	5.56	23

Adolescent Occupational Injuries Requiring Hospital Emergency Department Treatment: A Nationally Representative Sample

Larry A. Layne, MA, Dawn N. Castillo, MPH, Nancy Stout, EdD, and Patricia Cutlip

ABSTRACT

Data from a nationally representative sample of emergency departments for the 6-month period July through December 1992 were used to examine nonfatal occupational injuries sustained by adolescents aged 14 through 17 years. There were 679 occupational injuries, corresponding to an estimated 37 405 injuries nationwide. Males constituted 65.8% of the injury victims. The injury rate for males was 7.0 per 100 full-time employees, compared with 4.4 for females. Lacerations to the hand or finger accounted for 25.6% of all injuries. The majority of injuries occurred in retail trades (53.7%), which also had the highest rate (6.3 per 100 full-time employees). Seventy-one percent of the injuries in retail trade occurred in eating and drinking establishments. (*Am J Public Health.* 1994;84:657–660)

Introduction

Among affluent countries, the United States has the largest proportion of its children in the workforce.[1] Although the psychosocial effects of youth employment are controversial,[2–4] the potential for physical injury must be recognized. Castillo et al. report an occupational fatality rate of 5.1 per 100 000 full-time employees for 16- and 17-year-olds.[5] Many fatally injured youths were involved in activities prohibited by federal child labor laws.[5,6]

Several studies have examined nonfatal occupational injuries among adolescents.[7–14] The only published study that reported rates for the entire United States used 1982 data from the National Electronic Injury Surveillance System (NEISS). The rates for 16- and 17-year-olds, 8.2 per 100 full-time males and 3.0 per 100 full-time females, were exceeded only by the rates for 18- and 19-year-olds.[15]

In this study we use NEISS data to describe nonfatal occupational injuries sustained by youths aged 14 through 17 years in the latter 6 months of 1992 that required hospital emergency department treatment. National estimates are presented by age, sex, and industry divisions. The causes and types of injuries are also described.

Methods

The injury data reported here were extracted from NEISS, which is maintained by the Consumer Product Safety Commission (CPSC). NEISS contains information on product-related injuries collected from a national sample of 91 hospital emergency departments in the United States. Through a collaborative effort between the National Institute for Occupational Safety and Health (NIOSH) and CPSC, data on work-related injuries to persons aged 14 through 17 years have been collected since July 1992. This paper presents data for the first 6 months of surveillance, July through December 1992.

Hospitals participating in NEISS were selected from a probability sample of all hospitals in the United States and its territories, stratified by geographic area and hospital size.[16,17] Variances and confidence intervals were calculated on the basis of weighted estimates,[18] but CPSC recommends that confidence intervals not be calculated for weighted estimates of less than 1200. The numbers presented in the tables represent estimates for the number of injured adolescents in the United States for the entire 6-month period.

A work-related injury was defined as any injury sustained during work performed for pay or other compensation, regardless of eligibility for workers' compensation. Also included were injuries sustained during volunteer work for organized groups such as volunteer fire fighters, hospitals, and charity groups. Persons in the military were excluded from this analysis because employment data comparable to those of civilians were not available and the sample included cases from only one of the five military branches.

Industry information was coded according to the *Standard Industrial Classification Manual.*[19] The nature of the injury was derived directly from the physician's diagnosis.[20]

Although data were not available for the first 6 months of 1992, an estimate for the entire year was extrapo-

TABLE 1—Estimated Number and Rates[a] of Adolescent Occupational Injuries in the United States, by Age and Sex, July through December 1992

	Males		Females		Total	
Age, y	No.	Rate	No.	Rate	No.	Rate
14[b]	1028	. . .	274	. . .	1302	. . .
15	2904	6.7	1136	2.6	4040	4.7
16	7084	6.1	4352	4.7	11 436	5.5
17	13 583	7.6	7044	4.7	20 627	6.3
All	24 599	7.0	12 806	4.4	37 405	5.8

Note. Because each number represents one injured adolescent, the numbers were rounded to the nearest integer. Owing to this rounding, the numbers in the rows and columns may not add up to the exact number presented in the totals.
[a]Injury rates were calculated per 100 full-time employees; adolescents injured doing volunteer work were excluded from the rate calculations.
[b]Rates were not calculated because hourly employment data were not available for 14-year-olds.

TABLE 2—Estimated Number of Adolescent Occupational Injuries in the United States, by Body Part Injured and Nature of Injury, July through December 1992

	Nature of Injury						
Body Part	Laceration	Contusion or Abrasion	Sprain or Strain	Burn	Fracture or Dislocation	All Other	Total
Hand or finger	9560	2233	961	1620	614	1592	16 579
Leg, knee or ankle	1189	928	1638	420	356	423	4954
Head, face, or neck	1111	941	34	1092	0	1466	4644
Wrist or arm	853	961	1199	843	342	252	4449

Foot or toe	132	590	137	327	166	818	2171
All other	0	69	0	60	0	732	860
Total	12 896	6819	6042	4629	1555	5465	37 405

Note. Because each number represents one injured adolescent, the numbers were rounded to the nearest integer. Owing to this rounding, the numbers in the rows and columns may not add up to the exact number presented in the totals.

lated from the estimated number of adolescents injured from July through December 1992. To account for the seasonal variability of adolescent work, we assumed that the adolescent injury pattern for 1992 followed the same monthly patterns as for the years 1982 through 1986. Using the monthly distribution of adolescent injuries from previous surveillance, we computed an annual estimate for the entire year of 1992. (NEISS occupational injury data were collected by NIOSH for the years 1982 through 1986. These data were analyzed by month for workers aged 14 through 17 years for the 5-year period. The monthly weighted distribution was used to estimate the number of injuries that occurred during the first 6 months of 1992, a period for which data were not collected.)

In computing injury rates, labor force data from the Bureau of Labor Statistics' Current Population Survey were used as the denominator.[21] The Current Population Survey is a monthly national survey that includes employment information for persons as young as 15 years old. Employment data were converted to full-time employee equivalents.

Injury rates were not calculated for 14-year-olds because of the lack of hourly employment data. Because employment data from the Bureau of Labor Statistics do not include volunteer work, adolescents injured while performing volunteer work were not included in the rate calculations.

This study focuses on nonfatal injuries only. Data from emergency departments tend to underestimate fatal injuries because many victims of traumatic injury die before ever reaching an emergency department.[22] The NEISS system did not include any fatalities to adolescents during the period of this study.

Results

There were 679 occupational injuries to 14- through 17-year-old civilian workers reported in NEISS (July through December 1992). This number represents an estimated 37 405 (95% confidence interval [CI] = 28 000, 46 800) injuries nationwide to adolescent workers for the 6-month period. An estimated 297 (0.8%) of these injured adolescents were performing volunteer work; approximately 948 of the injured youth required hospitalization. It is estimated that about 64 100 (95% CI = 48 100, 80 200) work-related injuries to adolescents were treated in emergency departments during the entire year of 1992.

Table 1 shows the distribution of injuries and injury rates by age and sex for the 6-month period. Males accounted for a larger percentage of injuries (65.8%) and had a higher injury rate than females. The injury rate per 100 full-time employee equivalents for 16- and 17-year-olds combined (for comparison with rates found in other studies) was 7.0 for males and 4.7 for females.

Lacerations were the most common type of injury incurred (Table 2). Contusions and abrasions, sprains and strains, and burns constituted a larger proportion of injuries among females (56.5%) than among males (41.7%), although the injury rates for these three types of injuries were similar for both sexes. However, males' injury rate for fractures and dislocations was twice that of females (0.2 and 0.1, respectively, per 100 full-time employee equivalents); males' laceration rate was nearly twice that of females (2.0 and 1.2, respectively, per 100 full-time employee equivalents).

The hand or finger was the most frequently injured body area (44.3%) (Table 2). For males, 44.5% of injuries were sustained in the hand or finger; the proportion for females was 40.2%. The leg, knee, or ankle accounted for 10.6% of the injuries to males and 18.4% of those to females.

The industry division of retail trade accounted for 53.7% of all injuries and had the highest occupational injury rate

among adolescent workers (Table 3). The largest proportion of injuries in the retail trade industry (71.2%) occurred in eating and drinking establishments (Table 4).

The retail trade industry was characterized by high proportions of lacerations (39.0%) and burns (17.7%) (Table 4). Of laceration injuries in retail trade, a majority resulted from being struck by objects and striking against objects. Hand or finger injuries constituted more than one half of all injuries in retail trade; 84.1% of the injuries to the hand or finger were lacerations. Retail trades accounted for 3553 burn injuries, which primarily resulted from contact with hot objects (73.9%) and exposure to caustic substances (14.8%).

The second-largest number of injuries to adolescents occurred in the service industry. Nearly two thirds of the injuries in the service industry occurred in health services, amusement and recreation, and educational services. Contusion and abrasion injuries were overrepresented in services (30.0%, compared with 15.2% in all other industries) (Table 4).

The agriculture industry accounted for 6.7% of all injuries among adolescents. While lacerations and contusions or abrasions were the most common types of injuries in agriculture, fractures and dislocations were more prevalent in agriculture (14.4%) than in other industries (3.4%) (Table 4). One fifth of all agricultural injuries resulted from being caught in running machinery or equipment.

The manufacturing industry had the second highest injury rate (Table 3) and accounted for 4.0% of all occupational injuries among adolescents. Sprains and strains were the most frequent type of injury in manufacturing (32.3%, compared with 15.5% for all other industries). Forty-seven percent of the sprains and strains in manufacturing were to the hand or finger and 24.8% were to the leg, knee, or ankle.

An examination of the industry divisions by sex shows that a large percentage of injuries incurred by females were in the retail and service industries (Table 3). In agriculture, the proportion of injuries incurred by males was 87.7%, compared with 64.2% for all other industries; also, 40.0% of the injuries in agriculture were to 14- and 15-year-old males, compared with 12.4% for all other industries.

TABLE 3—Estimated Number and Rate[a] of Adolescent Occupational Injuries in the United States, by Industry Division and Sex, July through December 1992

Industry Division	No. Injuries			Injury Rate
	Male	Female	Total	
Retail trade	12 634	7453	20 087	6.3
Services	4049	3632	7681	4.1
Agriculture	2195	308	2502	4.3
Manufacturing	1013	485	1498	5.1
Construction	832	0	832	4.8

Note. Because each number represents one injured adolescent, the numbers were rounded to the nearest integer. Owing to this rounding, the numbers in the rows and columns may not add up to the exact number presented in the totals.

Discussion

We estimate that 64 100 of the nation's adolescents were treated in emergency departments for occupational injuries in 1992, and that adolescents have an injury rate of 5.8 per 100 full-time employee equivalents. These national estimates must be considered conservative because they are based on a

study of only injuries treated in emergency departments. Previous studies have found that about 36% of all work-related injuries are treated in emergency departments,[15] and fatal injuries are rarely included in emergency department surveillance.[22]

Adolescent occupational injuries can be prevented only once hazards have been identified and age-specific intervention strategies have been developed and incorporated into the industry's safety and training programs. Injuries reported in retail eating and drinking establishments accounted for the largest number of injuries in any industry subcategory, a finding supported by a study of workers' compensation cases in the state of New York.[9] Many of these injuries, particularly burns and lacerations, occurred in fast food establishments. Implementing methods to prevent burns in eating and drinking establishments, such as those previously recommended on the basis of detailed work-site inspections,[23,24] could prevent about 5650 adolescent occupational burns each year. Detailed studies and work-site investigations could identify prevention strategies in other sectors of retail trade,[11] services, manufacturing, and agriculture.

Although the injury rate in agriculture was not high in comparison with those in other industries, there was some indication that these injuries were more severe. Fractures and dislocations accounted for a higher percentage of the injuries in agriculture than in other industries. This finding is similar to findings from studies of adolescent workers' compensation claims.[9,12] Agricultural occupations declared hazardous by the secretary of labor are sanctioned for youth as young as 16 (and for even younger children working on their parents' farms).[25] In contrast, the minimum age for work declared hazardous in nonagricultural occupations is 18.[26]

There are many workplace risk factors that are unique to the adolescent workforce. Hayes-Lundy et al. found that length of employment is not related to injury experience among youth.[23] In addition, adolescents may be less familiar than adults with workplace hazards and safety awareness. Working youth, their parents, and employers must be informed about child labor laws, the risk of injury to adolescent workers, and the workplace hazards that exist in industries where adolescents are employed. □

Risk Factors for Violent Behavior in Elementary School Boys: Have You Hugged Your Child Today?

Jonathan L. Sheline, MD, MS, Betty J. Skipper, PhD, and W. Eugene Broadhead, MD, PhD

ABSTRACT

Seventeen Hispanic elementary schoolboys with violent behavior problems were compared with 27 matched control students who were not overtly violent at school. Violent boys were significantly more likely to not live with their fathers, to have unmarried parents, to have more siblings, and to have fathers who never show them affection. Parents of violent boys were more likely than those of matched control students to use spanking for discipline and to admit that they rarely express affection for their sons. (*Am J Public Health.* 1994;84:661–663)

Introduction

Violence is an especially serious public health problem in the United States, as evidenced by our homicide rate of 8.9 per 100 000 in 1988, the highest in the industrialized world (i.e., all of Europe, North America, southern South America, and the Pacific Rim countries).[1] Elementary school is one of the earliest settings in which we can study violent misbehavior. Longitudinal studies show that school truancy, fighting, or troublesome behavior as early as the first grade predicts similar behavior in high school[2] and predicts arrests for juvenile delinquency.[3–5] Juvenile delinquency, in turn, is associated with higher adult rates of arrests, violence, and drug use.[6–12]

Longitudinal studies of criminals find that the parenting practices associated with future delinquency include poor supervision or neglect by either parent,[13–17] overly harsh discipline by either parent,[10,13,14,16] and lack of affection by the mother[14,15] and/or father.[16] Despite this work, however, "the causal connection between the family and delinquency remains ambiguous and equivocal."[18(p263)] Most studies to date have suffered from the lack of a specific comparison group, the use of composite measures of family dysfunction instead of specific parenting practices,[11,14,15,19] and the use of legally defined juvenile delinquency as the outcome of interest when preventive intervention may be too late.

We report on a study of young schoolchildren, whose violent behavior was identified by their teachers rather than the court system, and of a rigorously matched control group. We studied minority, inner-city children, a population that has been neglected by all but one recent study.[20,21] Our purpose was to determine what specific parenting practices and family characteristics are associated with violent behavior in young schoolchildren.

Methods

Study Population

The study was conducted during the 1988/89 school year at a 530-student public elementary school in an inner-city, low-income, Hispanic neighborhood in Albuquerque, NM. A case–control study design was used. Case subjects were defined as students who received two or more infraction notices from teachers during the first semester of the school year for any of seven violent misbehaviors, including fighting, bringing dangerous items to school, and using gangs to intimidate others.

Two control students per case subject were selected from class lists, using the alphabetically nearest names that fit the matching criteria of having the same teacher, sex, ethnicity, and age within 1 year. Potential control students were excluded if they, or any of their siblings at the school, had been written up for a violent offense during the fall of 1988, or if they had enrolled late in school and had less time to accumulate offenses.

Questionnaires

All students in grades two through five filled out a 65-item questionnaire during class time, administered by their teachers with standard written instructions. Most questions used a Likert scale with three choices. Twenty-eight of the 65 items were adapted from a previously validated adolescent health survey[22]; the remainder were developed by the investigators. The questionnaire was field tested and revised using a convenience

TABLE 1—Student Questionnaire Variables with Significant[a] Difference in Responses of Case vs Control Subjects

Compared with Matched Control Students, Children Who Exhibit Violent Misbehavior in School Are More Likely to	Proportion[a] Case Subjects (n = 17)	Control Subjects (n = 27)	Matched Odds Ratio[b]	P
Not live with fathers	.53	.11	10.9	.026
Have parents who are not married	.59	.15	6.0	.022
Have fathers or male guardians who never show them physical affection	.31[c]	.00[d]	. . .[e]	.017[f]
Have fathers or male guardians who never express pride in or affection for them	.31[c]	.00[d]	. . .[e]	.017[f]
Report that they got at least one "bad note"	1.00	.56	. . .[e]	.0016[f]
Have more siblings (average no.)	4.1	2.4	NA	.026[g]

[a]Denominators may vary slightly; students were deleted from the study if they did not answer the question or if they had no match for the matched analysis.
[b]Calculated by conditional logistic regression.
[c]n = 16.
[d]n = 24.
[e]Matched analysis was not possible since no control is "exposed" or else all cases are exposed (in which case, the odds ratio would be infinity).
[f]Fisher's Exact Test, two sided.
[g]Student's *t* test, two sided.
*$P < .05$, two sided.

TABLE 2—Parenting Practices of Primary Caretakers of Violent Children vs Those of Matched Control Students

Behavior of Caretakers	Proportion[a] Case Subjects (n = 15)	Control Subjects (n = 20)	Matched Odds Ratio[b]	95% Confidence Interval
Occasionally or never express pride or affection to child	0.73	0.25	10.0	1.23, 86.0
Use spanking for discipline when child misbehaves at home	0.73	0.35	8.5	1.01, 71.0
Are not able to identify three things they like about child	0.53	0.21[c]	7.6	0.92, 64.0
Have no help taking care of children	0.27	0.10	4.4	0.44, 43.0
Occasionally or never show child physical affection	0.40	0.10	4.0	0.79, 20.0
Are not interested in discussing parenting skills with school counselor	0.57[d]	0.37[c]	3.2	0.62, 16.3
Are interested in discussing child's behavior with school counselor	0.71[d]	0.50[e]	2.4	0.44, 12.6
Let child watch more than 3 hours of television on school nights	0.40	0.25	1.9	0.43, 8.0

[a]Denominators vary slightly; caretakers were deleted from the study if they did not answer the question or if they had no match for the matched analysis.
[b]Calculated by conditional logistic regression.
[c]n = 19.
[d]n = 14.
[e]n = 18.

sample of two students from each grade. Kindergarten and first-grade students could not reliably answer the questionnaire and were excluded from the study.

In-home interviews using a 21-item questionnaire were sought from a parent or guardian of every case and control subject, and were conducted by six trained schoolteachers. The interviewers were blind to the case or control status of the child in 39 of 41 interviews.

Both questionnaires were developed in consultation with an adolescent psychiatrist and are available on request.

Analysis

Matched odds ratios were calculated with conditional logistic regression. Matching was broken for comparisons of continuous variables. When no control subjects were exposed to a given risk factor, Fisher's Exact Test was used.

Results

Study Participants

During the 78 school days of the first semester, 74 boys and 5 girls were given infraction notices for violent behavior. Of those, 48 boys and 4 girls got only one notice for a violent offense and were thus excluded from the study to provide a clearer demarcation between case and control subjects. After 4 children in kindergarten and first grade were excluded, 22 boys and 1 girl remained eligible for study. Six of the 23 had moved, including the 1 girl, leaving 17 male case subjects.

Two control students per case subject were desired, but six case subjects had only one classmate who met the matching and exclusion criteria for controls, and one control student was excluded later because of an incomplete questionnaire; this left 27 control students. Parent interviews were completed by the parent or guardian of 16 of the 17 case subjects and 25 of the 27 control students.

Risk Factors for Violent Behavior

Compared with matched control students, children who exhibited violent misbehavior in school were 11 times as likely not to live with their fathers and 6 times as likely to have parents who were not married; they also had almost twice as many siblings. Their fathers (or male guardians, for those who did not live with their fathers) were significantly more likely never to show them physical affection and never to express pride in or affection for them (Table 1).

Responses to questions on parenting practices were counted only if the parent or guardian interviewed said he or she was the primary caretaker of the child, thereby yielding 15 case and 20 control subjects. Table 2 shows re-

sponses for all questions on parenting practices. The primary caretakers of the 15 violent children were significantly more likely than those of the 20 matched control students to report that they rarely or never expressed pride or affection to their child and that they used spanking for discipline when the child misbehaved at home.

Discussion

Early violent behavior in the second through fifth grades is correlated with both structural and functional family characteristics in this low-income, largely Hispanic population. The small sample size limits this study's power to detect significant differences. The cross-sectional ascertainment of exposures precludes inferences about cause and effect.

The finding that violent boys got less affection from their male guardians may be confounded by the finding that violent boys were much more likely not to be living with their fathers. Indeed, it has been shown that stepparenthood is the single most powerful risk factor for child abuse.[23] When the analysis was restricted to only those boys who lived with their biologic fathers, violent boys were still almost twice as likely as matched control subjects to have fathers who never hugged them or expressed verbal affection, but this was not statistically significant.

This study focuses on a minority population and addresses aspects of family influences on high-risk behaviors at a very early age when intervention may be feasible. Our data show that boys from families with absent fathers, divorced parents, or numerous siblings are at higher risk for violent behavior. Recent studies have shown that family demographic factors, including single parents and low socioeconomic status,[24,25] have little or no effect on future delinquency after controlling for poor parenting.[16,26,27] The parenting practices most strongly associated with violent behavior in our study were lack of affection shown by either parent, especially fathers, and use of spanking for discipline. Intervention trials are urgently needed to evaluate how programs that encourage and enable parents to show more affection affect children's behavior and to teach parents to use disciplinary measures other than spanking. □

Acknowledgments

This research was supported by a Health of the Public grant to the University of New Mexico from the Pew Charitable Trusts and the Rockefeller Foundation, and by a US Public Health Service grant, 5 D32 PE14010–12, to Duke University.

The authors would like to express their warmest appreciation to the students and staff of the elementary school for their enthusiastic participation in this research. Special thanks go to the school's nurse, Mrs Gloria Sandoval, RN, and to administrative assistant Mrs Carol Vigil. Thanks also go to Drs Arthur Kaufman, Lloyd Michener, Maurice A. Hitchcock, and Ross Snyder for their suggestions and review of the manuscript.

• The central factor in increased risk was the high frequency of sexual relationships outside the regular partner relationship. These "steppin' out" relationships contributed to considerable "gamesmanship" in both women and men, covering up both the behavior and resulting sexually transmitted diseases. Yet the quantitative data indicated that people were far more optimistic about an intervention effort aimed at reducing sexual partners than they were about increasing condom use (although this result was stronger among women).

On the basis of these results, a community-based, peer-oriented program for small, mixed-gender groups was designed. The aim of the program is to reduce the number of sexual partners and to strengthen the primary relationship when one is present. Trained peer counselors will facilitate small group discussions, presentations, and activities aimed at increasing individual self-esteem, individual and mutual responsibility, and understanding between men and women. The intervention program will provide information about sex and sexual health and present positive role models and relationship models for men and women. Approximately $100 000 in funding is being sought for a 2-year period to develop, test, evaluate, and modify three rounds of the intervention.

The delineation of focal subareas and subpopulations permits a broader range of methodological tools that can be used by local health department staff and can be linked more directly to program development. These tools include the collection of qualitative data directly from members of the target population, linked to the use of focused surveys with a relatively small sample size. The combination of qualitative and quantitative data provides mutual verification, stimulates new lines of discovery, and improves the specificity of data collection methods and instruments. It requires less time, personnel, and expense than more traditional methods of community health evaluation and need assessment. The development and testing of the method were carried out as part of a larger contract between the University of Connecticut and the Connecticut Department of Health Services and accounted for $40 000 of the larger contract. Personnel included a half-time project coordinator, four part-time key informant interviewers who were members of the targeted subpopulation, and three student data processors who abstracted information from the sexually transmitted disease reports.

The methodology encourages the participation of many sectors of the community, including the funding source, the sponsoring organization, other community-based service providers, and the focal population. Maximizing the participation of each of these sectors in the research process contributes to their commitment to the results and to the development and implementation of an intervention. The data collection procedures called for require input from a trained researcher (we would suggest the involvement of local university faculty) but maximize the involvement of health department and community people in design, data collection, and analysis.

This research approach can serve to redefine the role of the university as a community partner and the role of the local health department not only as an effective user of data but as a generator of data in its search for the local solutions that are so much a part of public health tradition. □

The Rhode Island Sun Smart Project: Skin Cancer Prevention Reaches the Beaches

Skin cancer is by far the most common malignancy in the United States. More than 600 000 Americans will be affected this year, exceeding the number affected by the next four most common sites combined.[1] Solar ultraviolet radiation has been identified as the major cause of the epidemic. Because most ultraviolet radiation exposure is intentional, primary efforts to prevent skin cancer must focus on encouraging individual precautionary behaviors. The beach in summer is a site of special concern, inasmuch as exposure to solar ultraviolet radiation is particularly intense for many people at this time and place.

The purpose of the Rhode Island Sun Smart Project was to deliver skin cancer prevention and health promotion efforts directly to sunbathers at Rhode Island (population: 1 000 000) beaches. A 1-year grant of $35 000 from the National Cancer Institute provided initial funding for the development of measurement models and questionnaires based on the transtheoretical model of behavior change.[2-4] A subsequent 2-year grant of $50 000 from the Rhode Island Cancer Prevention Research Consortium provided funding for the development of interventions and feasibility testing of the beach as an intervention site. Interventions were conducted at one of three Rhode Island state beaches on 11 days during the summers of 1991 and 1992. Rain, forecasts of rain (resulting in poor beach attendance), cold weather, and a hurricane caused us to abandon attempts on 9 additional days in 1991 and 2 days in 1992. Project staff included a health psychologist, a dermatologist, a graduate research assistant, a project coordinator, and six trained interviewers.

Seven interventions were developed and tested:

1. An *educational pamphlet* (*Skin Care under the Sun*,[5] developed by the American Academy of Dermatology) described the hazards of sun exposure and appropriate precautionary behaviors. Pamphlets were distributed in conjunction with all other interventions.

2. Free *sunscreen samples* were distributed to beachgoers with verbal instructions from the interviewers on proper use. The samples were donated to the American Cancer Society by the manufacturer and consisted of 4-oz bottles of a waterproof sunscreen in an emollient base with a sun protection factor (SPF) rating of 15.

3. The *sun sensitivity assessment and feedback* intervention consisted of a few simple questions that assessed intrinsic ("phenotypic") sun sensitivity, an important indicator of skin cancer risk.[6] Feedback describing appropriate preventive actions specific to the participant's degree of risk (high, moderate, or low) was preprinted on adhesive labels and attached to the educational pamphlet.

4. The *sun scanner* intervention consisted of a mirror and a "black light" (Wood's light) in a cloth-enclosed box into which the participant looked. Wood's light is a low-intensity source of blue and near-ultraviolet light that accen-

tuates epidermal pigmentation, dramatizing the extent of ultraviolet damage and photoaging—the cosmetic consequences of chronic sun exposure on the face. The scanner was loaned to the Brown University Dermatoepidemiology Unit free of charge from the manufacturer through the American Academy of Dermatology.

5. Both *educational* and *dramatic videotape* interventions were used. *Skin Care under the Sun* (American Academy of Dermatology) is a 7-minute staged discussion between a mother and her teenaged daughter about the dangers of sun exposure and the necessity for precautions. *Goodbye Sunshine,* a 20-minute segment from the Australian *60 Minutes* television program, recounts the story of a young man who devoted himself to informing the public about the dangers of sun exposure and the importance of early detection of skin cancer until his death from melanoma.

6. The *skin microtopography* intervention required making a plastic impression, similar to a dental impression, of the skin in the crow's-feet area near the eye. These impressions can be graded according to the degree of wrinkling, a manifestation of sun-induced aging of the skin. We chose not to implement this intervention after pilot testing indicated that it would be very difficult to conduct in the beach environment.

7. The *ultraviolet* and *polarized light instant photography* interventions were developed for year 2 of the project to circumvent limitations of the sun scanner and microtopography interventions, respectively. The ultraviolet light camera was used to take a full frontal black-and-white photograph of the face, revealing epidermal pigmentation damage similar to that shown by the sun scanner. The polarized light camera was used to take a close-up color photograph of the crow's-feet area that revealed structural damage to the skin.

Each intervention was conducted at least twice at different beaches and on different days. The selected beaches had distinct "personalities": a teen beach, a family beach, and a community beach. Permission for beach access was obtained from the Rhode Island Department of Environmental Management. Beach staff at all sites were very supportive, often asking to participate in the interventions and volunteering to reorganize the available space to accommodate our needs.

A $500 lottery incentive was offered to recruit participants, although many beachgoers reported that the lottery did not influence their decision to participate. The interviewers were easily spotted on the beach; they wore matching white hats, sunglasses, bright yellow T-shirts printed with the Sun Smart logo and the names of the project sponsors (the University of Rhode Island, Brown University, and the American Cancer Society). The T-shirts legitimized the project while serving as an additional informative intervention. The Sun Smart logo consists of a sun (located in the center of the T-shirt) that has in each ray a slogan or word associated with safe sun behavior (*sunglasses, Slip! Slop! Slap!, SPF15+, hat, shirt*). The intervention staff modeled appropriate sun behavior, captured attention, and promoted interaction. The local broadcast and print media took notice of the project, resulting in coverage on evening news broadcasts and follow-up newspaper stories.

A total of 1016 beachgoers were contacted during the 11 days of testing. Overall participation was high (62%, n = 633), with a median acceptance rate of 89% (range: 21%–96%). Participation was higher than 80% for all interventions except the videotapes (see Table 1). Although videotape would seem to be an important and convenient means of public health education, there are barriers to its use at the beach. These barriers include the need for access to electrical power in an area out of direct sunlight, the requirement that participants leave the beach and come to the pavilion area for an extended period of time, and the inevitable delays (which discouraged participation) for some individuals because the videotape cannot be shown until a reasonable number of people have gathered to watch. In addition, the only beach well-equipped for this intervention (the teen beach) also had the lowest acceptance rates for other interventions.

Participation was much higher for the remaining interventions. The acceptance rate for the sun scanner is especially noteworthy, as the scanner shared many of the limitations of the videotapes, such as the need for access to electrical power and the requirement that sunbathers leave their place on the beach to go to the pavilion area. The sun scanner drew much curiosity, dramatic reactions, and many questions from participants. The sun sensitivity assessment required only 2 minutes to complete, was delivered directly to participants on the beach, and provided immediate feedback. The sunscreen intervention was also well accepted; it was easy to deliver, it was free to participants, and it gave immediate access to sun protection.

TABLE 1—Participation Rates for Beach-Based Interventions (n = 633)

	No.	Acceptance, %[a]
Intervention		
Photographs	80	95
Pamphlets	98	95
Sun sensitivity assessment	137	90
Sun scanner	76	83
Sunscreen	126	81
Videotapes	116	27
Beaches		
Community	164	92
Family	121	86
Teen	348	50

[a]Percentage of individuals offered the intervention who agreed to participate.

The highest participation rates were obtained for the pamphlet and photography interventions. The photography interventions, especially the ultraviolet light photographs, generated a great deal of interest among sunbathers. Although in some ways not quite as compelling as the "real time" image provided by the sun scanner, the photographs had several important advantages. In particular, the photos were directly deliverable to sunbathers on the beach and provided a convenient and highly personalized take-home reminder of the consequences of unprotected exposure to solar ultraviolet radiation. Furthermore, project participants who showed their photographs to family and friends help to disseminate an important public health message.

Participation rates also varied by beach site (see Table 1). The relatively low rate for the teen beach underscores the difficulty of reaching the adolescent population, an important target group for "safe sun" messages.

On the basis of our experience, we recommend a beach intervention package consisting of pamphlets, sunscreens, sun sensitivity assessments, and photographs. Excluding the research and

evaluation components of our project, we estimate a cost per participant of about $30. Costs could be reduced by soliciting contributions of pamphlets and sunscreens and by enlisting the cooperation of local departments of health or volunteer agencies such as the American Cancer Society. Economy of scale would offset relatively costly one-time expenses (e.g., equipment). We are also exploring the development of computer-based expert systems to provide follow-up interventions for the home.[7] Pending continued funding, we intend to conduct further pilot testing of our intervention package.

The Sun Smart Project has demonstrated the feasibility of the beach as a site for skin cancer prevention and health promotion efforts that reach individuals at high risk for skin cancer. Perhaps our biggest concern in conducting this project was that beachgoers would not want to be bothered while spending a relaxing day in the sun with family and friends. In fact, many sunbathers were bored and looking for something to do. The Sun Smart Project also provided valuable data pertinent to assessing which interventions are viable at the beach and identifying barriers to implementation in larger public health efforts. Results continue to be analyzed to assess readiness of the interventions for public health dissemination. □

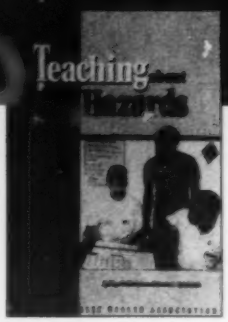
The Practical Guide to Teaching Workers about Job Hazards



Teaching about Job Hazards: A Guide for Workers and Their Health Providers

By Nina Wallerstein, DrPH, and Harriet Rubenstein, JD, MPH.
170 pages, softcover, 1993

Occupational disease and injury are vast and growing health problems; however, they are almost 100% preventable with appropriate worker education in health and safety. This practical manual gives guidelines on providing health and safety education to workers who face on-the-job hazards. It contains actual worksheets, tips, case studies, and ideas that can be used immediately. Intended for readers who are already familiar with occupational health.

Contents: Guidelines for Worker Education; Educating Individual Worker-Patients; Developing a Training Workshop; Providing Education in Conjunction with Screenings; Preparing Factsheets and Training Materials; Developing Training Sessions for Workers with Low Literacy and Limited English Proficiency; Teaching Adults: Guidelines for Using Various Methods; Evaluating Health and Safety Education; Additional Prevention Activities; Occupational Health and Training Resources; Sample Training Materials: Factsheets, Activities, Training Agendas; Recommendations for a Basic Worker and Community Occupational Health Library; A Basic Occupational Health Library for Primary Care Providers. American Journal of Public Health

The *American Journal of Public Health* (*AJPH*), published monthly, is the official Journal of the American Public Health Association, Inc, 1015 15th St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005. *AJPH* allotted $40; *The Nation's Health* allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters. Printed in the United States.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on the first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, *AJPH* Reprints, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the Journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Chronic Neurological Sequelae to Organophosphate Pesticide Poisoning

Kyle Steenland, PhD, Barbara Jenkins, MA, Richard G. Ames, PhD, Michael O'Malley, MD, MPH, David Chrislip, BA, and John Russo, PhD

ABSTRACT

Objectives. This work was undertaken to determine whether there are any chronic neurological sequelae to acute organophosphate pesticide poisoning.

Methods. California surveillance data were used in a study of neurological function among 128 men poisoned by organophosphate pesticides in California from 1982 to 1990 and 90 referents. Tests included a neurological physical examination, 5 nerve conduction tests, 2 vibrotactile sensitivity tests, 10 neurobehavioral tests, and 1 postural sway test.

Results. After correcting for confounding, the poisoned group performed significantly worse than the referent group on two neurobehavioral tests (sustained visual attention and mood scales). When the data were restricted to men with documented cholinesterase inhibition (n = 83) or to men who had been hospitalized (n = 36), the poisoned subjects also showed significantly worse vibrotactile sensitivity of finger and toe. Significant trends of increased impairment were found with increased days of disability on a wide spectrum of tests of both central and peripheral nerve function.

Conclusions. While these findings are limited by low response rates and by small sample sizes for specific pesticides, this study was based on a large surveillance database and is the largest study to date of the chronic effects of organophosphate pesticide poisoning. The evidence of some long-term effects of poisoning is consistent with two prior studies. (*Am J Public Health.* 1994;84:731–736)

Introduction

Organophosphate pesticide poisoning results in well-known acute effects, which typically end in a few days. These effects are caused by the binding of cholinesterase and the buildup of acetylcholine. According to data assembled from poison control centers, there are approximately 10 000 cases of organophosphate pesticide poisonings annually in the United States.[1]

Some organophosphates may also cause a delayed-onset peripheral neuropathy several weeks after exposure, which primarily affects the extremities. Symptoms may persist or gradually decrease. This peripheral neuropathy results from severe inhibition of neuropathy target esterase, causing axonal degeneration.[2,3]

The literature is sparse as to whether an acute poisoning followed by apparent recovery has any subsequent chronic neurological effects. Two epidemiological studies with reasonable sample size and control series have indicated deficits among poisoned subjects on various neurobehavioral tests.[4,5] To investigate further the chronic sequelae of acute organophosphate poisoning, we conducted a study of 128 men aged 16 and over who were poisoned by an organophosphate pesticide in California between 1982 and 1990. We studied neurological function via neurobehavioral tests, nerve conduction tests, vibrotactile sensitivity tests, a test of postural sway, and a neurological physical examination.

Methods

Study Population

The state of California requires physicians to report known or suspected cases of organophosphate pesticide poisoning.[6] The pesticide illness reports generated by this system contain detailed information about patients' medical history and exposure; such information was collected from poisoned individuals and their employers during an investigation conducted by the Agriculture Department of the county where the poisoning occurred. Information is available regarding whether a patient was hospitalized as well as the number of days the patient took off from work (disability days) subsequent to the poisoning. In most cases, the report lists the specific pesticide thought to be responsible for the poisoning ("primary" pesticide), as well as any other pesticides to which the patient was exposed at the time of poisoning.

Case subjects (the "exposed" group) were the systemic organophosphate pesticide poisonings between 1982 and 1990 among men aged 16 and older (excluding suicide attempts). Women were not included owing to small numbers (15% of eligibles) and anticipated increased difficulty in tracing. All subjects had been exposed to one or more organophosphate pesticides and had sought medical attention (28% had been hospitalized for at least 1 night). Cases were divided into two types, "definite" and "probable." Definite

Kyle Steenland, Barbara Jenkins, David Chrislip, and John Russo are with the National Institute for Occupational Safety and Health, Cincinnati, Ohio. Richard G. Ames and Michael O'Malley are with the California Environmental Protection Agency in Berkeley and Sacramento, respectively.

This paper was accepted January 24, 1994.

TABLE 1—Comparison of Poisoned vs Nonpoisoned Subjects

	Poisoned (n = 128)	Nonpoisoned (n = 90)
Mean age, y (SD)	33.8 (9.5)	29.5 (10.9)*
Mean grade level (SD)	9.6 (4.9)	10.6 (3.6)
Mean body mass index (SD)	27.3 (4.4)	26.8 (4.7)
Race[a]		
Hispanic, %	56	56
White, %	41	39
Other, %	3	5
Preferred language[b]		
English, %	70	66
Spanish, %	30	34
Current smokers, %	37	33
Current drinkers, %	66	72
Mean hours of sleep, night before testing (SD)	7.2 (1.7)	7.2 (1.5)
Mean cups of coffee/tea on morning of test (SD)	0.8 (1.1)	0.9 (1.0)
Mean no. of drinks, night before testing (SD)	1.5 (2.7)	1.8 (2.4)
Average year of poisoning	1986	NA
Self-reported solvent exposure, %	20	21
Current employment in agriculture,[c] %	40	19*

Note. NA = not applicable.
[a]Self-reported.
[b]Language chosen for computerized neurobehavioral test; 18 subjects did not take this test.
[c]Nonpoisoned subjects were required to not be currently exposed to pesticides; nonpoisoned men in agriculture denied current exposure.
*Significant difference between groups at $P = .05$.

cases (n = 83) were those reporting one or more symptoms compatible with organophosphate poisoning (flulike symptoms, headaches, nausea, diarrhea, salivation), accompanied by a documented inhibition of red blood cell or plasma cholinesterase. Inhibition had to be at least 20% below the subject's own baseline value or be a value considered below the normal range by the testing laboratory. Probable cases (n = 45) did not have data on cholinesterase inhibition but reported either (1) compatible symptoms accompanied by relative specific physical signs—for example, bradycardia (heart rate less than 60) or miosis (narrowing of pupils to 3 mm or less); or (2) compatible symptoms accompanied by a history of direct exposure to the skin or eye during an application or spill. Virtually all subjects had been exposed occupationally.

Subjects were traced via the address in the pesticide illness report, telephone directory assistance, and current addresses obtained from the Internal Revenue Service. Social security numbers were not available. Subjects were contacted by phone and mail and asked to participate by coming to a central location in California, spending the night in a hotel, and taking a 4-hour battery of tests the following day. They were excluded if they had diabetes, had suffered a stroke, or had experienced trauma that had affected their central nervous system. Subjects were paid $100 for their participation and reimbursed for their expenses.

A nonexposed comparison group consisted of friends of the subjects not currently working with pesticides. The nonexposed individuals were also paid $100 for their participation. Participation was voluntary for all subjects, and consent forms were obtained.

Tests of Neurological Function

All tests were performed by technicians "blind" to exposure status.

Nerve conduction tests for peripheral neuropathy were done on three nerves of the dominant arm (median motor, median sensory, and ulnar sensory) and two nerves of the dominant leg (peroneal motor and sural sensory) using a standard protocol.[7,8] Two measures of nerve function were made: (1) conduction velocity—the amount of time from stimulation to the onset of principal depolarization (latency), divided by distance; and (2) peak amplitude—the size of the maximal response of the compound action potential for sensory studies or the M-wave for motor studies.

All tests were performed with surface electrodes; stimulation consisted of 100 to 200 microsecond square pulses. Motor responses were orthodromic; sensory tests were antidromic. Surface temperature of the limb was maintained at 33.0°C (centigrade) for the upper limb and 32.0°C for the lower limb.

Sensitivity to vibration was tested as a measure of the possible axonal degeneration in the sensory nerves of the index finger and big toe (dominant side, five trials). Vibrotactile thresholds were measured with the Vibration II instrument via the "method of limits."[9]

Eight computerized neurobehavioral tests from the Neurobehavioral Evaluation System (NES2, version 4.22) were conducted.[10] These tests were available in English and Spanish. While generally self-explanatory and requiring little intervention by the investigator, they did require a reading level equivalent to an elementary school education. The eight tests used are listed below:

1. Mood scales (affect test). Measures subjects' self-reported transient states of tension, depression, anxiety, fatigue, and confusion.
2. Finger tapping (motor speed test). Measures how many times a key can be repeatedly struck in 30 seconds, using the preferred hand.
3. Sustained visual attention (continuous performance test). Requires pressing a key quickly when a certain letter appears amid a temporal sequence of various letters; 60 letters appear in 5 minutes.
4. Hand–eye coordination (visuomotor accuracy test). Measures the degree of error in tracing a moving sine curve with a cursor.
5. Simple reaction time (visuomotor speed test). Measures how fast one can respond to a visual stimulus by pushing a button.
6. Symbol digit (coding speed test). Requires matching digits to symbols as fast as possible following an exhibited matched pattern.
7. Pattern memory (visual memory test). Requires selecting a previously seen pattern out of three similar patterns.
8. Serial digit learning (learning/memory test). Requires memorizing and replicating a series of eight digits as quickly as possible.

In addition, two noncomputerized neurobehavioral tests of psychomotor function—the Santa Ana dexterity test and the pursuit aiming test—from the World Health Organization core battery of tests were used.[11] These tests require turning rows of successive pegs 180 de-

[a]All models had a variable for nonpoisoned vs poisoned. Models for nerve conduction velocity (NCV) and amplitude included age, race, and body mass index. Models for vibrometry included age, weight, race, and height. Models for computerized Neurobehavioral Evaluation System tests included age, education (grade), and test language (Spanish or English). Models for pursuit aiming and Santa Ana tests included race, age, and education. Models for postural sway included race, age, education, height, and weight.

[b]Coefficient represents difference in outcome between poisoned and nonpoisoned. Performance of poisoned vs referents, + = better; − = worse.

[c]*P* values are for tests of the null hypothesis that the coefficient equals 0. The actual values of the outcome variables, adjusted for covariates, may be obtained by request from the authors.

[c]*P* values reported if ≤.10.

[d]For mood scales, a higher score meant more tension, depression, etc., interpreted here as a worse performance.

[e]The difference in sway for eyes shut vs eyes open (higher scores represent worse performance).

grees and using a pencil to mark a point inside each of a series of circles as quickly as possible.

A computerized measurement of postural sway (30 seconds), a quantitative analogue of the Romberg clinical exam, was conducted to measure central nervous system function.[12] The outcome is the difference in sway between measurements taken with eyes open and eyes closed.

Finally, a physician conducted a standard neurological physical examination designed to detect gross neurological abnormalities and asked the subject about past medical history. The exam, which screened for primarily motor and cerebellar function, was used primarily to exclude subjects who suffered neuropathies from causes unrelated to pesticides, such as trauma or stroke.

Analysis

Thirty-eight poisoned subjects (30%) did not bring a friend to serve as a nonexposed comparison. Data were analyzed without reference to pair matching both to avoid loss of poisoned cases in the analyses and to facilitate multivariate analyses permitting control of unmatched confounders. All outcome measures were continuous variables; multivariate linear regression was used. Among the potential confounders considered were age, race (self-reported), body mass index (weight in kilograms/height in meters squared), education (grade level), preferred language, hours of sleep and alcohol consumption the evening prior to the test, smoking habits, use of prescription medicine, medical history, current exposure to solvents or pesticides (self-reported), and coffee consumption the morning of the tests. Multivariate models for nerve conduction velocities and amplitudes included race, age, and body mass index. Regressions for computerized neurobehavioral tests included age, grade level, and language in which the test was taken (Spanish or English); those for vibrotactile sensitivity and postural sway included age, race, weight, and height. All models were checked for assumptions of normality of residuals and model fit.

A dichotomous variable indicating poisoned case or referent was the principal exposure variable included in most

Note. NCV = nerve conduction velocity.

[a]"Days taken off from work" was entered as a continuous variable in models, replacing the dichotomous (poisoned/nonpoisoned) exposure variable used in other models. There were 18 poisoned men excluded from the analysis because they were missing data for days taken off from work. Referents were assigned "0" for this variable.
Thirty eight poisoned men had 0 days taken off from work and were grouped with the referents; arbitrary assignment of 1 day off from work for these 38 did not change results. Models included days taken off from work and relevant confounders (see Table 2).

[b]Performance of those who took more days off from work: + = better; − = worse.

[c]P values are for tests of the null hypothesis of no trend in outcome with days of work, and are reported if $P \leq .10$.

TABLE 4—Number of Poisoned Cases, by Type of Pesticide[a]

Pesticide	Primary[b]	Some Exposure
Chlorpyrifos	10	17
Diazinon	11	19
Dimethoate	7	14
Demeton methyl/ oxydemeton methyl	3	21
Mevinphos	13	39
Parathion	5	8
Phosalone	20	20
Other—specified	19	NA
Undetermined	38	NA

Note. NA = not available.

[a]Taken from original pesticide illness report.

[b]For most poisoned cases, a primary pesticide suspected of causing the poisoning was listed in the record, but for 38 poisoned subjects no primary pesticide was specified. In addition to the primary pesticide, many men were also exposed concurrently to another organophosphate, which could possibly have contributed to the poisoning (here listed under "some exposure"). All subjects in the category "primary exposure" for a pesticide are included in the category "some exposure" for that pesticide.

models. Analyses were also conducted in which the dichotomous exposure variable was replaced by a variable for number of days taken off from work (disability) subsequent to poisoning, with 0 days assigned to referents.

Although there were numerous outcomes, no formal correction for multiple comparisons was made[13]; instead, statistically significant associations were evaluated for coherence and consistency.

A number of individuals were excluded for all or some tests. The first 16 individuals tested did not have this mood scales test on the computerized neurobehavioral battery since this test was added after the first round of testing. Eighteen subjects (13 poisoned subjects and 5 nonpoisoned subjects, $P = .15$) did not take the computerized neurobehavioral tests, most often because their reading ability was insufficient. Other subjects were excluded in lesser numbers from specific tests for reasons such as malfunction of equipment, trauma affecting the nerves, and frostbite.

Results

We tested 128 poisoned and 90 nonpoisoned subjects. The 128 poisoned men represented 31% of the target population of 416 potential participants. Of the remaining potential participants, 13% refused, 37% could not be located, and 19% could not be contacted. (Although addresses were provided, mailings elicited no response from this latter group, and no phone number was listed with directory assistance.) A comparison of the 128 poisoned participants with the 288 poisoned nonparticipants revealed that nonparticipants were slightly older, were more likely to be Hispanic, and took more days off from work following their poisoning (data not shown).

Table 1 shows that poisoned and nonpoisoned subjects were generally similar but that poisoned subjects were significantly older and somewhat less educated.

Table 2 compares all poisoned subjects, definitely poisoned subjects, and hospitalized subjects with the 90 nonpoisoned subjects. For all poisoned subjects, the only statistically significant differences from the nonexposed group (at the $P = .05$ level) occurred for the test of sustained visual attention (continuous performance) and for two mood scale tests. For the 83 subjects with definite poisonings (documented cholinesterase inhibition), vibrotactile sensitivity for both finger and toe was also significantly worse. For the 36 hospitalized subjects (1 or more nights), vibrotactile sensitivity, the sustained attention test, and the symbol digit test were significantly worse than they were for the referents.

Table 3 shows the results of analyses by days taken off from work (disability days), which ranged from 0 to 32 for poisoned subjects (mean = 3.8, SD = 5.5). Significant trends of increased impairment with increased days of disability were found for peroneal nerve conduction velocity, for finger vibrotactile sensitivity, and for 5 of 10 neurobehavioral tests.

Variables for current employment in jobs with potential pesticide exposure and for years of self-reported past exposure to pesticides were tested but were not generally associated with the outcomes, nor did their inclusion in the model alter results for the effect of poisoning.

Analyses of the data according to year of poisoning did not change results, indicating that observed positive associations were not restricted to those subjects who were poisoned more recently.

Table 4 indicates the distribution of poisonings by pesticide, based on the original pesticide illness reports. As previously noted, these reports list a primary pesticide involved in the poisoning, as well as other pesticides to which a subject was exposed that might have played a role in the poisoning. In some cases, no one pesticide was deemed primary.

Table 5 shows the results of pesticide-specific analysis. For primary pesticides, chlorpyrifos- and phosalone-poisoned subjects showed some decrement in peripheral nerve function.

Table 5 also presents results for subjects exposed to any of seven pesticides at the time of poisoning, regardless of whether that exposure was considered the primary cause of the poisoning. Poisoned men who had been working with demeton methyl (Metasystox) showed a variety of decrements compared with the nonexposed men. (Eighteen of 21 men exposed to demeton methyl or oxydemeton methyl had no primary pesticide listed.) Similar findings for mevinphos may be partly owing to the fact that one third of the men working with mevinphos were also working with demeton methyl (13/39). Findings were unremarkable when analyses were restricted to those whose primary pesticide was mevinphos.

TABLE 5—Significant Associations ($P \leq .05$) in Analyses of Neurological Function, by Primary Pesticide or by Some Exposure to a Pesticide[a]

Primary[b]	
Phosalone[c]	More tension ($P = .05$) and fatigue ($P < .01$) on mood scales, better Santa Ana dexterity test ($P = 05$), worse sural amplitude ($P = .02$)
Diazinon	No associations
Chlorpyrifos	Worse peroneal motor nerve conduction velocity ($P = .04$) and ulnar sensory amplitude ($P = .03$)
Mevinphos	No associations
Some exposure	
Parathion	No associations
Diazinon	More tension on mood scales ($P = .04$)
Chlorpyrifos	More tension on mood scales ($P = .02$, worse finger vibrotactile sensitivity for the definitely poisoned ($P = .003$, n = 8)
Dimethoate	More tension ($P = .02$) and fatigue ($P = .05$) on mood scales
Mevinphos	Worse finger vibrotactile sensitivity ($P = .01$), worse performance on sustained attention test ($P < .01$)
Demeton methyl[d]	Worse finger ($P < .01$) and toe ($P = .01$) vibrotactile sensitivity; worse sustained attention ($P = .03$), simple reaction ($P = .04$), and symbol digit ($P < .01$) tests; more tension ($P = .05$) on mood scales

[a]Models used were the same as those used for Table 3, with same referent group (n = 90). Information on pesticide exposure at time of poisoning came from the original pesticide illness report.
[b]Analyses were restricted to the four primary pesticides with the most cases (nine or more).
[c]Phosalone only occurred as a primary pesticide.
[d]Demeton methyl and oxydemeton methyl (Metasystox and Metasystox-R) combined.

Note. + = better performance; – = worse performance. NA = not available.
*$P < .05$.

Discussion

For the neurobehavioral tests used in this study, we found significantly worse performance on 2 of 10 tests (mood scales and the sustained visual attention test) by poisoned subjects, worse performance on a third test (symbol digit) by hospitalized subjects, and significant trends of worse performance on 5 of 10 tests by those who took more days off from work after poisoning. Increased impairment for those with presumably more severe poisonings (those hospitalized and those who took more days off from work) tends to support the hypothesis that the observed deficits on some of the neurobehavioral tests may be causally related to past poisonings. Two prior studies have also found that poisoned men performed significantly worse on a broad spectrum of neurobehavioral tests.[4,5] Table 6 compares our findings with those of two previous reports for six such tests. Our findings may be viewed as reasonably consistent, although the prior studies found a broader spectrum of deficits among poisoned subjects than we did. As most of the poisoned subjects in these studies had been hospitalized, they may have represented more severe poisonings.

Regarding the peripheral nervous system, nerve conduction velocities and amplitudes were not significantly worse for poisoned men overall. For pesticide-specific analyses, there were some significant deficits in nerve conduction velocity

and/or amplitude observed among men poisoned by chlorpyrifos or phosalone. This is consistent with a case report of delayed-onset neuropathy following poisoning by chlorpyrifos.[14]

Vibrotactile sensitivity of finger and toe was significantly reduced among poisoned men with documented cholinesterase inhibition, among poisoned men who had been hospitalized, and among men who took more days off from work after poisoning. Pesticide-specific analyses suggest that demeton methyl was the pesticide most associated with the vibrotactile sensitivity deficit among the poisoned men. A case report of delayed-onset neuropathy following poisoning by demeton methyl has been previously published.[15] A finding of vibrotactile sensitivity deficit in the absence of significant slowing of nerve conductions may reflect the relative insensitivity of electrophysiologic measures for the detection of a distal axonopathy.[16]

There are a number of limitations in our data. Our relatively low response rate may have affected our results in unpredictable ways. We anticipated difficulty in locating poisoned subjects, a number of whom were migrant Mexican workers. Possible conservative biases could have occurred if those subjects who did not participate were more likely to have had neurological impairment, but the opposite scenario is also possible. The use of friend controls could have also biased our findings toward the null if friends were selected for this similarity to the poisoned subjects regarding the outcomes under study (overmatching); however, a bias in the opposite direction could occur if the friends are more sociable people with better neurobehavioral capability.

Another limitation is the low proportion of variation explained by our predictor variables, indicating that individual heterogeneity or other environmental factors that we did not measure played a large role in determining the neurological outcomes of interest. It is possible that other unmeasured variables may have acted as confounders in our data. It should be noted that other studies using these tests have shown a similar low proportion of variation explained. A final limitation is the small sample size for pesticide-specific analyses, limiting our power to detect significant results.

Despite these limitations, our study is the largest to date of neurological function among both subjects previously poisoned by organophosphate pesticides and appropriate referents. It has the additional advantage of being population based, with a strict definition of cases.

In conclusion, we did not find apparent symptomatic damage to the neurological function of men poisoned in the past by organophosphate pesticides, but we did find some evidence of injury to the peripheral nerves as reflected by decreased vibrotactile sensitivity. We also found some evidence of deficits in central nervous system function as reflected by worse performance on 2 of 10 neurobehavioral tests. Furthermore, performance on a number of neurobehavioral tests was significantly worse for those with more severe poisonings, with severity measured by either hospitalization or number of days taken off from work subsequent to poisoning. □

Acknowledgments

This study was conducted as a collaborative effort between the State of California and the National Institute for Occupational Safety and Health (NIOSH). Financial support was provided partly by the US Environmental Protection Agency.

Drs Joseph Arezzo, Ann Fidler, and Jerry Blondell offered helpful comments on the manuscript. Numerous NIOSH employees contributed to this study: Dr Ray Alderfer, Dr Geoffrey Calvert, Dr Tony Suruda, Karen Davis-King, Nina Baird, Steve Brightwell, Robert Dick, Marie Haring-Sweeney, Kathy Watkins, Chris Gersic, Jean Geiman, Bettie Walpole, Bill Ehling, Rose Watkins, and Patty Gudlewski. Aurelio and Rosa Marta de los Santos recruited subjects and translated. Laura Weiss (Cal EPA) helped collect data. Nada Elmore, Jean Wilhite, and Pat Koenig (Biotrax) performed nerve conduction tests.

Health Status Differentials in the People's Republic of China

James Sutherland Lawson, MD, MHA, and Vivian Lin, DrPH

ABSTRACT

Objectives. This study sought to demonstrate that health status varies markedly in different parts of China.

Methods. The main source of data was statistics compiled by the Chinese Ministry for Public Health for 1978 to 1990 regarding causes of death. However, because mortality statistics in China are based on localities that have the capacity to provide data, they are not entirely representative. The international classification of disease categories was also used, together with anatomically based disease descriptions. Rates were calculated using the 1982 and 1990 population censuses.

Results. Death rates differ markedly between urban and rural areas. Deaths due to infectious diseases, respiratory diseases, pregnancy and childbirth, and injuries and poisoning are much higher in rural areas; those due to pertussis, dysentery, typhoid, hepatitis, rabies, and anthrax are much more common in the apparently poorer provinces. Schistosomiasis remains a major problem in some provinces. Goiter and cretinism are still major diseases in many parts of China, especially those areas with iodine deficiency.

Conclusions. Cause-of-death patterns in Chinese cities are similar to those of industrially developed countries such as Australia, Japan, and the United States. Such patterns in the poorer rural areas are much more typical of those of developing countries. (*Am J Public Health.* 1994; 84:737–741)

Introduction

Since the 1949 revolution and the consequent establishment of the People's Republic of China, the improved health status of the Chinese people has been dramatic. The significant achievements in this regard, both nationally and in some specific localities such as Shanghai,[1,2] have been widely acknowledged and documented.[3,4] Those achievements have been measured by increased life expectancy, decreased infant mortality, and reduced morbidity. Specifically, life expectancy increased from about 35 to 70 years between 1949 and 1990, and the overall death rate declined from approximately 20% to 6% of the population per year during the same period.[5] This decline in deaths appears to be primarily owing to the reduction in infectious diseases.[6]

Despite these improvements, health status varies markedly in different parts of China. Deaths due to all major causes are from 10% to 100% higher for specific age groups in rural as compared with city populations. In addition, deaths due to infections remain high in many provinces. These variations may be explained by the substantial differences in both geography and socioeconomic development across China.

Methods

Sources of Data

For the most part, data used in this paper are from statistics compiled by the Chinese Ministry of Public Health for 1978 to 1990.[7] Death rates are reported for gender and age groups by *International Classification of Disease* (ICD) categories and are based on the 1982 and 1990 population censuses and a 1% sample survey of the population in 1987.

A number of points need to be made about the use and interpretation of these data. First, informants in the Ministry of Public Health suggest that there may be some differences in diagnostic and classification approaches in China despite the use of ICD codes. Accordingly, we have presented selected tables as published in the original Chinese form. This selection of data is based on both the need to simplify a large volume of material and the interest in women of childbearing age.

Second, local quality control in the collection and reporting of statistics is likely to vary, and the localities included are probably those that are above average in their capacity to collect data. Thus, the data probably come from those areas of China with better health status. Nonetheless, these are the most reliable and comprehensive data currently available to non-Chinese persons.

Geographical Classifications

The geographical classifications are as follows:

1. Large cities: 16 cities, including Beijing, Tianjin, Shanghai, Nanjing, Guangzhou, Xian, and Wuhan;
2. Medium and small cities: 25 cities, including Suzhou, Hefei, Xiamen, Guilin, and Taiyuan;
3. Class I rural areas: 35 localities, including rural suburbs of Beijing, Tianjin, and Shanghai, and se-

lected cities and counties of Zhejiang and Jiangsu provinces;

4. Class II rural areas: 35 counties in Jiangxi, Hubei, Hunan, Guangdong, Fujian, and Sichuan provinces;
5. Class III rural areas: 9 counties selected from Guizhou, Anhui, and Gansu provinces.

Formal statistics about levels of income and education with respect to these geographic classifications were not available. However, it is obvious from firsthand observation that these levels are much higher in the large cities and class I rural areas than they are in medium and small cities and particularly in class II and III rural areas. At one extreme, the larger cities are the commercial, industrial, administrative, and cultural centers of China; at the other extreme, the provinces from which the class III areas are chosen are the poorest, most backward provinces in China. To offer some perspective, data from Australia, the United States, Japan, and India are also presented.

Results

Overall Death Rates

The 1988 age-adjusted death rates (for men and women) for the urban and rural areas by ICD codes are shown in Tables 1, 2, and 3. However, although the Chinese authorities use ICD codes, they do so with "Chinese characteristics"—namely, the frequent and continued use of anatomical classifications—which sometimes precludes meaningful international comparisons.

Death rates between urban and rural areas differ markedly. Of particular note are those differences in infectious diseases, respiratory diseases, digestive diseases, problems of pregnancy and childbirth, conditions of the perinatal period, and injuries and poisoning. While men are at greater risk of death from infectious diseases, malignant neoplasms, conditions of the perinatal period, and injuries and poisoning, women appear to be at slightly greater risk of death from endocrine, nutritional, and immune disorders and heart disease.

The most striking differences within urban areas are the higher death rates in small and medium cities due to pregnancy and childbirth, infectious diseases, respiratory diseases, and injuries and poisoning, and the higher death rates in larger cities due to neoplasms, conditions of the perinatal period, heart disease, and cerebrovascular diseases. The male/female differentials remain similar to the overall picture.

The differences in death rates between rural areas are dramatic. The gradient from class I to class III is steeply upward for infectious diseases, respiratory diseases, digestive diseases, pregnancy and childbirth among women, and, among men, injury and poisoning. There is also a reverse gradient in rural areas from class I to class III for malignant neoplasms and cerebrovascular diseases. The differential between different classes of rural areas is greater than that between large and medium/small cities.

The death rate for China as a whole was 6.28% for 1990 (calculated from the 1990 census). However, this rate varied

considerably between provinces and autonomous regions. For example, death rates were 5.4% in Beijing, 5.3% in Guangdong, 6.4% in Shanghai, 7.1% in Sichuan, 7.7% in Yunnan, and 9.2% in Tibet. These death rates (which are not age standardized) tend to reflect differing levels of socioeconomic development in specific areas.

The death rate due to infectious diseases is at historically low levels in all parts of China (1.2 per 100 000 in 1990). However, there are considerable regional variations, with deaths due to pertussis, dysentery, typhoid, hepatitis, rabies, and anthrax being much more common in poorer provinces such as Guizhou and Tibet than elsewhere in China. Schistosomiasis remains a major problem with 400 326 cases detected in 1989, more than half of which were in Hubei Province.

Goiter and cretinism are still major diseases in many parts of China. In 1989 there were 6 054 000 known patients with goitrous disease and 199 033 patients with cretinism. These conditions occur in the iodine-deficient regions, particularly in mountainous areas such as Xinjiang, Zhejiang, Fujian, Hubei, Guangxi, and Qinghai.

Deaths associated with pregnancy and childbirth appear to be high (compared with those in industrially developed countries). Based on surveys of such deaths conducted in 1989, maternal mortality rates per 100 000 females per year were 49.9 in urban areas and 114.9 in rural areas. Pre- and postpartum hemorrhage, hypertension, heart disease, pueperal fever, and amniotic embolism were the most frequent causes of maternal death.

International Comparisons

As shown in Table 4, there are several major differences in patterns of causes of death between China, the United States, Australia, and Japan. Deaths due to infectious diseases (particularly tuberculosis), stroke, bronchitis and emphysema, accidents, suicide among women, and maternity are higher in China; those due to cancer are lower in China than in Japan, the United States, and Australia.

As shown in Table 5, there are major differences in causes of death between China and India. Whereas the available data use anatomical classifications and are not age standardized, the pattern of deaths shown for India remains typical of that for a developing country, whereas that for China reflects a "transitional" stage in the rural areas.

Discussion

Despite reservations about the accuracy of the data, particularly as the most reliable information inevitably has come from China's more developed cities and provinces, the patterns of disease and injury as shown in the tables are a good reflection of firsthand observation. Traffic crashes are commonly seen; unsafe water, unsafe occupational health and safety practices, and unsafe food preparation are obvious to all visitors. In addition and most importantly, the nationwide experience has been confirmed in detail by epidemiological field studies conducted in the Shanghai area in the early 1980s.[2]

This review of mortality data clearly demonstrates that, despite dramatic improvements in the health status of the Chinese people during the past 40 years, a substantial burden of sickness and premature death remains. This burden does not affect the population equally. Deaths among infants due to respiratory infections, diarrheal diseases, and accidents are up to 10 times more common in poor rural communities than in large city populations. Maternal deaths are high by international standards and are also much more common in poor rural areas. Deaths due to infectious diseases generally, as well as to tuberculosis and respiratory infections in particular, are high for all of China but are much higher in the rural areas.

The incidence of trauma is also massive, with approximately 500 000 deaths per year; this has recently been addressed by Li and Baker.[11] Because of the vast population, the number of daily deaths due to traffic crashes and other trauma in China is equivalent to two fully laden jumbo jets crashing each day!

In both city and urban populations, coronary heart disease, cerebrovascular disease, and cancer are the most common causes of death among 65- to 70-year-old persons. A longitudinal study of adults in Shanghai by Chen et al.[12] has confirmed these trends. Unfortunately, and again because of the vast population, these deaths tend to hide the continuing problems of infectious diseases, trauma, and maternal deaths outlined above.

Tobacco consumption is rapidly rising in China, in parallel with a rapid rise in lung cancer. This issue has recently been addressed in detail by Yu et al.,[13] who regard the increased Chinese tobacco consumption as an "impending catastrophe."

Apart from maternal health programs, women's health issues have largely been unrecognized in China. Of particular significance and sadness are the reports of high female infant death rates owing to drowning, mechanical suffocation, and homicide. This may provide evidence to support anecdotes about female infanticide, especially in light of China's population policy. At later ages, the high rate of suicide suggests that the quality of life for women, especially given the social pressures confronting them, still means that "women's liberation" is more rhetoric than reality.

The current health status of the Chinese people largely reflects the current social and economic development in different parts of China. The much higher health status of Chinese urban dwellers can be accounted for by the higher education, more regular and varied food supplies, better sewerage, better housing and water supplies, better developed medical services, and better access to health services than is found in poor rural areas. Indeed, statistics about hospital beds, immunization, and running water all reflect similar differentials.[6] For instance, in the largest cities of Beijing and Shanghai, there are more than 4.5 hospital beds per 1000 population; immunization levels among 18- month-old infants is well over 90%; and more than 80% of these populations, including 50% of the nearby rural populations, have running water. In the relatively developed provinces of Jiangsu, Fujian, Hunan, and Yunnan, the number of hospital beds per 1000 population is above two, the immunization level is more than 90%, and 40% to 80% of the population (and 20% of the rural population) have access to running water. However, in the least developed provinces such as Guizhou, Gansu, and Anhui, the number of hospital beds per 1000 population is below two, immunization levels are below 80%, and only 20% to 50% of the population (and 10% of rural population) have access to running water.

In the 1980s, the Chinese health care system underwent significant changes as part of the overall economic reforms.[14,15] These changes may have exacerbated the wealth differential between the larger coastal cities and the hinterland. As the larger coastal cities have become "open," there has been a rapid increase in their standard of living and health care investments. Additionally, changes in agricultural policy and the rural economy have meant significant improvements in the standard of living for those areas close to the large cities. Many class I rural areas during the decade became absorbed into (or contiguous with) the urban communities; hence, large cities and rural class I share many similarities in death rates.

From the perspective of health status, China as a whole can be regarded as in transition, halfway between being an economically developed, industrialized country and being a poor developing country. Rural China is currently experiencing rates of infectious diseases, maternal deaths, and accidents typical of India and Africa, while urban China is experiencing rates of heart disease, stroke, and cancer typical of the United States, Japan, and Australia. In summary, the patterns of disease in urban China are typical of more developed countries and those patterns in rural China remain typical of developing countries.

The massive issue of population growth, although not considered in this article, is of major relevance to China's economic development and health status. If current trends continue, China's population is expected to rise from 1 200 000 000 in 1991 to approximately 1 500 000 000 by 2025, at which point the level might stabilize.[16] This growth in population implies a need to house, feed, and provide services for an additional population equivalent to that of the United States during the next 30 years.

The Chinese leadership has developed health policies[17] that seek to address these problems. These policies include improving the quality of drinking water, the techniques of birth, the hygiene of food supplies, and health services management; increasing hospital services and the number of medical graduates; and focusing on the prevention of infectious diseases.

The data presented in this paper suggest that several additional priorities could be addressed. These are (1) the need for vigorous anti-tobacco policies to reduce the problems of lung cancer and respiratory disease, (2) enhanced trauma prevention activities, and (3) development of programs aimed specifically at women's health issues. □

Pap Smear and Mammogram Screening in Mexican-American Women: The Effects of Acculturation

Lucina Suarez, MS

ABSTRACT

Objectives. For Mexican Americans, acculturation is a multidimensional process of adopting attitudes, values, and behavior from the non-Hispanic White culture. This study examines the effects of different dimensions of acculturation on the cancer screening behavior of Mexican-American women.

Methods. Subjects were 450 randomly selected Mexican-American women age 40 years and older living in El Paso, Texas. Personal interviews solicited information on age, income, education, health insurance, Pap smear and mammogram use, and acculturation. Acculturation was measured with five scales that assessed English proficiency, English use, value placed on culture, traditional family attitudes, and social interaction.

Results. The 2-year prevalence of Pap smear and mammogram screening increased with each gain in acculturation on English proficiency and use. These associations disappeared when adjusted for age, income, insurance, and education. After adjusting for sociodemographic factors and other acculturation dimensions, a strong traditional Mexican attitude toward family was positively related to mammography use.

Conclusions. Taking advantage of the positive influence of Hispanic familism on cancer screening behavior may increase the effectiveness of cancer control interventions in Mexican Americans. (*Am J Public Health.* 1994;84:742–746)

Introduction

Participation in breast and cervical cancer screening programs among Hispanic women must be improved. Of the three major ethnic and race groups in the United States (Non-Hispanic Whites, Blacks, and Hispanics), Hispanic women are the least likely to utilize Pap smears and mammograms.[1–3] The 1987 National Health Survey showed that Hispanic women age 18 years and older were twice as likely as Black women and three times as likely as White women to have never had a Pap smear.[1] Among women age 40 years and older, fewer Hispanic women (16%) than Black women (18%) or non-Hispanic White women (24%) have had a mammogram in the prior 3 years. Of the three major US Hispanic subgroups (Cuban, Puerto Rican, Mexican American), Mexican Americans are the least likely to use preventive health services in general.[4] Most studies among the Mexican-American population show that the lower rates of cancer screening are primarily associated with lower education levels, lack of health insurance coverage, and lower income levels.[2–5] Apart from these socioeconomic factors, others suggest that acculturation and assimilation levels of Mexican-American women are barriers to more frequent use of cancer screening tests (e.g., Pap smears and mammograms).[2,4]

Published studies examining factors other than socioeconomic factors have shown that high acculturation on English language use is associated with greater recency of Pap smear screening or mammography.[2,4,5] Only two of these studies have examined acculturation dimensions other than language. In a study of 603 Hispanic women age 55 years or older living in public housing projects in Los Angeles, in which four dimensions of acculturation (language preference, country of birth, contact with homeland, and attitude about children's friends) were examined, only language was associated with Pap smear and mammogram screening.[6] In a large-scale study based on the 1982–1984 Hispanic Health and Nutrition Examination Survey, acculturation measures were limited to language use (the only predictor of screening), ethnic identification, and generation status.[4] These studies confirm the importance of language but provide little information on the effect of cultural attitudes and values on the cancer screening behavior of Mexican-American women.

Acculturation—a process in which individuals whose primary learning has been in one culture (Mexican American) adopt attitudes, values, and behaviors from another culture (non-Hispanic White)—has many more dimensions than language use. English language use measures in some way functional integration into the non-Hispanic White society (i.e., assimilation), but it does not necessarily measure new attitudes or values. Country of origin or generational status of an individual by its unchanging nature fails to fully measure the continuous process of acculturation and assimilation. Depending on region of the country, neighborhood, and immigrant experience, a first-generation Hispanic American may be more acculturated and assimilated than a second- or third-generation Hispanic American.[7]

This paper was accepted July 7, 1993.

The development of effective interventions for Mexican-American women requires understanding the effect of different dimensions of assimilation and acculturation on cancer screening behavior. The present study examines the influence of acculturation and assimilation on the cancer screening behavior of Mexican-American women living in a large Southwestern border community. In addition to structural assimilation, which includes both language use and social interaction with members of mainstream society, the effect on screening behavior of the two separate acculturation dimensions of cultural values and family attitudes was examined in light of other socioeconomic barriers.

Methods

The sample included 450 Mexican-American women age 40 years and older living in 16 census tracts along the United States-Mexico border in El Paso County. In 1990 the population within these 16 census tracts was at least 90% Hispanic and had a median income at or below the federal poverty threshold. All households in the study census tracts were identified by using the Polk city directory and the *1990 Census Tract City of El Paso Street Code Reference Manual.* A listing of street addresses by tract was used to randomly select 1300 households as a sampling frame to screen for Mexican-American women age 40 years and older. From this sampling frame with household enumeration, 549 households were identified as having at least one eligible woman for inclusion in the survey. Only one eligible woman from each household was interviewed. The decision rule for selecting from two or more eligible women was to interview the woman who had the most recent birthday because this information was on the enumeration form and was easy to determine. Of these households, 20 women were not available for an interview, 76 refused to give an interview, and 3 women gave incomplete interviews. Four hundred fifty women completed personal interviews for a response rate of 82.0%.

After determining whether the respondent preferred to be interviewed in Spanish or English, bilingual interviewers used a standard instrument to ask women their age, annual household income, education, health insurance coverage, Pap smear and mammogram screening practices, and questions related to structural assimilation and acculturation. Acculturation was measured by using previously published scales developed by Hazuda et al.[8] that assessed the following dimensions of assimilation and acculturation: adult proficiency in English, adult pattern of English vs Spanish language usage, value placed on preserving Mexican cultural origin, attitude toward traditional family structure and sex-role organization, and adult interaction with members of mainstream society. The scales have demonstrated construct validity, are applicable to Mexican-American populations, and provide measures of acculturation that are independent of each other.[8]

TABLE 1—Percentage Distribution of Mexican-American Women Age 40+ Years, by Acculturation Level, El Paso, Texas, 1991

		Acculturation Level			
	No.	Low 1	2	3	High 4
English proficiency	447	44.3	14.3	17.0	24.4
English vs Spanish usage	444	64.6	16.4	15.5	3.4
Value placed on cultural origin	442	27.6	35.3	26.0	11.1
Attitude toward traditional family	444	21.6	40.3	37.4	0.7
Interaction with mainstream society	444	56.1	30.4	12.6	0.9

Women were assigned a summary score on each dimension by adding response scores for items under each acculturation scale. Within each dimension, women were grouped into four levels rank-ordered from least to most acculturated based on previously defined cut points from the San Antonio Heart Study.[9] The use of these cut points, rigorously determined from a large population sample of Hispanics and non-Hispanic Whites, provides a standard method of measuring acculturation across different populations (e.g., El Paso and San Antonio). Location in the higher-numbered levels represented acculturation toward non-Hispanic White culture. For example, women in the highest level for proficiency in English were highly proficient in understanding, speaking, and writing English. Women in the highest level for English vs Spanish language pattern used mostly English when interacting with family, friends, neighbors, and coworkers, and they watched, listened to, and read English media. For value placed on preserving Mexican cultural origin, women in the highest level thought it was not important for children to know the history of Mexico, follow Mexican customs, or celebrate Mexican holidays. For attitude toward traditional family structure and sex-role organization, women in the highest level thought it was not important that family members know their family tree, have close ties to extended family, remember deceased family members, have married children live close to parents, or concede authority to father or brothers. For women in the highest level of interaction with members of mainstream society, the majority of their close friends, neighbors, and coworkers were non-Hispanic Whites.

Cancer screening history was ascertained from responses to the following questions: (1) Have you ever had a Pap smear (mammogram)? (2) When did you have your most recent Pap smear (mammogram)? Women were categorized according to whether or not they reported a Pap smear or mammogram in the previous 2 years. Pap smears or mammograms performed because of a health problem were considered diagnostic exams and were excluded. Thus, the outcome of interest was the use of screening Pap smears or screening mammograms as routine prevention services in the absence of symptoms.

Chi-square tests, including tests for trends, were performed to assess differences in prevalence of Pap smear and mammogram screening across various levels of sociodemographic factors and acculturation dimensions. With use of multiple logistic regression, odds ratios of having a screening Pap smear or screening mammogram within the previous 2 years were computed for each gain in acculturation level. Test-based 95% confidence intervals were computed with the software EGRET.[10] Univariate odds ratios and their 95% confidence intervals were computed for each acculturation dimension. Odds ratios and confidence intervals then were adjusted for relevant sociodemographic factors: age (10-year intervals), education (less than 7th grade, less than high school, high school graduate), income (don't know, <100% federal pov-

erty level, <200% federal poverty level, >200% federal poverty level), employment (no, yes), and health insurance (none, medicaid/medicare, private). To eliminate confounding among acculturation dimensions, the final model for each dimension of acculturation included as covariates all other acculturation dimensions (levels 1–4) and sociodemographic factors.

Results

Eighty percent of the women in the study were interviewed in Spanish and 61% were born in Mexico. Only 18% of the women had graduated from high school, 84% had incomes below the federal poverty level, and 45% had no health insurance. Seventeen percent had never had a Pap smear and 65% had never had a mammogram. The median age was 57 years. Sixty two percent of the women were married, and only 17% were employed outside the home. As shown in Table 1, the distribution of women in the study along the five dimensions of acculturation varied widely. Based on the percentages of women in the highest acculturation level, women tended to be more acculturated on English proficiency (24.4%) and personal value placed on preserving Mexican cultural origin (11.1%). The El Paso women in the study were far less acculturated on English language use (3.4%) than on English proficiency (24.4%), which is perhaps not surprising in a border community. Fewer than 1% of the women were highly acculturated with regard to attitude toward traditional family structure and sex-role organization and interaction with members of mainstream society.

Table 2 shows differences in prevalence of Pap smear and mammogram screening in the previous 2 years by various sociodemographic characteristics. The percentage of women who had a recent screening Pap smear declined with each 10-year age group ($P < .05$). Mammogram screening levels for all age groups were consistently low. Women with lower education and income levels were screened less often for cervical and breast cancer. Women on Medicare or Medicaid were least likely to be screened by a Pap smear, even compared with women who have no insurance (a group who may have access through public health clinic gynecologic services). That was not true for mammography; women with no health insurance were least likely to be screened.

The prevalence of Pap smear and mammogram screening by acculturation levels is shown in Tables 3 and 4. The prevalence of Pap smear and mammogram screening increased with each successively higher level of acculturation on proficiency in English and English vs Spanish usage. The other three acculturation dimensions failed to have significant linear effects on Pap smear and mammogram screening. On one dimension, attitude toward traditional family structure and sex-role organization, women did not show the expected pattern of increased screening with greater acculturation. Women least acculturated with regard to traditional family ties had slightly higher rates of Pap smear and mammogram screening.

Because each dimension of acculturation was associated with one or more

socioeconomic characteristics, the independent effect of each acculturation dimension after adjusting for sociodemographic factors was assessed by using multiple logistic modeling. Tables 5 and 6 show the unadjusted and adjusted odds ratios (and their 95% confidence intervals) of screening for each level gain in acculturation. The association of English proficiency and English vs Spanish language usage with Pap smear and mammogram screening disappeared or was reduced when adjusted for age, income, insurance, and education. With all acculturation dimensions and sociodemographic factors in the model, only age remained a statistically significant factor and was inversely related to Pap smear screening ($P = .03$). The strongest independent factor affecting mammogram screening was health insurance coverage ($p = .001$). After adjusting for sociodemographic factors and the other acculturation dimensions, a woman's attitude toward traditional family structure had an independent effect on, and was inversely related to, mammogram screening. Women least acculturated with regard to traditional Mexican family attitudes (importance of extended family and male primacy) were more likely to have been screened by a mammogram.

Discussion

Although the importance of assimilation in explaining the underutilization of Pap smears and mammograms in Mexican-American women is generally acknowledged, no study has demonstrated an independent effect of Mexican cultural attitudes or values on cancer screening behavior. This study confirms the often-observed finding that language use is an important factor in identifying groups of Hispanic women in need of cancer screening services.[2,4,6,11] In this study the effects of English language proficiency and use disappeared when adjusted for income, education, and health insurance coverage, suggesting a strong correlation with these sociodemographic factors. Therefore, language preference, proficiency, and use measure access to services and are proxies more of socioeconomic status than of cultural attitudes and values.

An important finding of this study is the independent positive effect of Mexican family attitudes and values on mammogram screening. The few studies of Hispanic women and screening behavior have not evaluated cultural values or family attitudes.[2,4,6,11] In a study of elderly Hispanic women living in Los Angeles, recency of mammogram was more frequent in those who had high homeland contact compared with those who had low homeland contact after adjusting for education and age.[6] An interpretation that those women with more homeland contact had stronger family ties provides

more evidence for the positive effect of family on screening. Why Mexican-American women with stronger traditional family attitudes would avail themselves of mammogram screening more frequently may be explained by the support provided by extended family ties either through emotional well-being or shared economic resources. Pap smear screening was not as strongly associated with family attitudes as mammography was. That may be due to the more prevalent use of Pap smears compared with the relative newness of the mammogram in this population.

The same positive effect of family on mammogram screening might also be evident in non-Hispanic women if family attitudes were measured. However, the acculturation scale of family attitudes used in this study was chosen because of its ability to discriminate non-Hispanic White attitudes from Mexican-American attitudes.[8] Family and familism are core characteristics of Hispanic culture.[12] Individuals can acculturate and assimilate remarkably well on language proficiency and use, come to value US traditions more than Mexican traditions, and still retain strong family ties and a high level of perceived family support.[8,12]

The significant effect of family attitudes was demonstrated in a border population not as highly acculturated as the population in San Antonio, Texas, where the acculturation scale was developed.[8] Mexican-American women living in El Paso may not be representative of other US Hispanic populations; in El Paso the Hispanic culture is as dominant as the non-Hispanic culture. It is important to investigate whether this familial effect is observed in Hispanic populations with greater variation on this dimension.

Hispanics are the fastest-growing population in the United States, and Mexican Americans are by far the largest ethnic group. Studies to improve cancer screening in this population consistently equate cultural differences with barriers to screening. This study identifies the positive influence on mammogram screening behavior of one important cultural attribute. Designing effective cancer control interventions for Mexican-American women not only requires taking advantage of the role of family in this group but also should encourage retainment of these cultural values. Future studies should examine this association in other Hispanic populations and, more importantly, examine how the role of familism can be used to change health behavior. □

Risk Behavior and Correlates of Risk for HIV Infection in the Dallas County Household HIV Survey

Geraldine M. McQuillan, PhD, Trena M. Ezzati-Rice, MS, Arlene B. Siller, BS, Wendy Visscher, PhD, and Peter Hurley, BS

ABSTRACT

Objectives. The Dallas County study of a proposed national household seroprevalence survey was designed to assess the feasibility of conducting a national survey and to estimate the prevalence of human immunodeficiency virus (HIV) and hepatitis B virus infection for Dallas County. Risk behavior data were collected and correlated with HIV infection.

Methods. Participants in this survey represented a probability sample of the county. A self-administered questionnaire on demographic characteristics and HIV risk behavior was completed and a blood sample was obtained.

Results. Of the 1724 adults eligible for the survey, 1446 completed the questionnaire and 1374 provided a blood sample. The prevalence estimates were 0.4% for HIV and 7.3% for hepatitis B virus. A strong relationship was observed between HIV and hepatitis B status and risk behavior.

Conclusions. In this study population, receptive anal intercourse and increasing numbers of male partners had the strongest correlation with the prevalence of HIV and hepatitis B virus infection in men. The high level of risk reporting for individuals positive for HIV or hepatitis B suggests that survey participants who engage in risk behaviors were willing to report those behaviors. (*Am J Public Health.* 1994;84:747–753)

Introduction

Estimating the magnitude and direction of the spread of human immunodeficiency virus (HIV) in the general population is of considerable public health interest. However, as reported by Massey et al.,[1] there are numerous technical and methodological issues involved in obtaining a direct estimate of the rate of HIV infection in the general population. Estimates of the size of HIV risk groups, their distribution in the population, and their relationship to HIV infection can be useful in modeling the HIV/acquired immunodeficiency syndrome (AIDS) epidemic; they can also be useful for effective planning and allocation of resources for educational and prevention programs to reduce the numbers of persons engaging in HIV risk behaviors.

The Dallas County Household HIV Survey, sponsored by the National Center for Health Statistics (NCHS), Centers for Disease Control and Prevention (CDC), was conducted in fall 1989 by the Research Triangle Institute. In addition to assessing the technical feasibility of a national household HIV survey, the Dallas study, which used a probability sample of the county, was designed to estimate the extent of HIV infection among adults 18 to 54 years of age. Further, the survey was designed to provide information on the distribution of HIV risk behaviors and correlates of risk among subgroups of the population for use in planning local HIV prevention and treatment programs.

In addition to estimates of self-reported risk behaviors and correlates of risk, this paper examines the relationship of HIV and hepatitis B virus prevalence estimates for selected subgroups of the population defined by demographic characteristics and risk behavior. Antibody to hepatitis B core antigen, a serologic marker for past or present infection with hepatitis B virus, was included in this survey as a surrogate measure to help evaluate the level of risk behaviors reported. These data, based on a representative sample, provide information on HIV infection and risk behaviors for noninstitutionalized adults in Dallas County.

Methods

Sample Design and Selection

The target population was residents of households of Dallas County, which was selected for the study because it had a sufficiently high AIDS case rate and its population size could yield for analyses an adequate number of HIV-positive persons who were 18 to 54 years of age and not on active military duty. The survey used a stratified area probability design, with all households in the county having a chance of selection. The sampling frame was based on the count of housing units from the 1980 census, updated to be representative of Dallas County in 1989. The area sampling frame was geographically stratified by race/ethnicity, sex, and marital status and by expected level of HIV risk. The construction of three HIV

[b]Sex and marital status were missing for one sample person each among persons giving blood; sex was missing for one sample person; marital status was missing for two sample persons among persons completing the questionnaire.

risk strata (high, medium, or low) was based on summary public health statistics of HIV risk indicators, including sexually transmitted disease prevalence and AIDS case distribution.[2] This stratification by expected HIV risk level was designed to ensure that both high- and low-risk persons would be adequately represented in the sample. The sample was balanced within each of the three risk strata so that the proportion of Black, Hispanic, and White households was approximately equal to the overall race/ethnicity distribution in Dallas County. A detailed description of the sample design has been published elsewhere.[2]

Survey teams consisting of an interviewer and a phlebotomist visited each sample household to determine if it contained at least one eligible adult. One person was selected at random from each age-eligible household. After agreeing to participate, sample persons were asked to complete a 10-minute self-administered questionnaire containing basic demographic questions as well as questions about behaviors related to the risk of HIV infection; individuals were asked to report those behaviors practiced since 1978 and within the past 12 months. Respondents either completed the questionnaire in private or had the interviewer read the questionnaire to them while they marked their own answers. The certified phlebotomist then drew a blood sample.

Risk-behavior data and blood sample results were not linked to personal identifiers. Other strict privacy procedures implemented in the survey to ensure a completely anonymous dataset have been previously described.[2] Sample persons who provided both a blood sample and a completed questionnaire in the regular survey received a $50 cash payment. In addition to the regular survey, a special quality assessment study was conducted following the main survey in an attempt to increase the overall survey response rate and to provide data for assessing and adjusting for potential nonresponse bias.[2] Data from both the regular study and the quality assessment study are combined for the analyses in this paper.

Laboratory Analyses

Laboratory analysis of the sample included assays for HIV antibody (enzyme-linked immunosorbent assay, Dupont, Inc) and for the antibody to hepatitis B core antigen (Abbott Laboratories, North Chicago, Ill). Any reactive specimen for HIV antibody was retested and confirmed by Western blot analysis (Dupont, Inc).[3]

Statistical Analyses

Estimates of the prevalence of selected HIV risk behaviors for persons aged 18 to 54 years in Dallas County are based on sampling weights that were adjusted for household screening and sample person nonresponse. To adjust for nonresponse, basic sampling weights were first corrected to compensate for screening and questionnaire nonresponse. A further nonresponse adjustment was made in the weights for the HIV and hepatitis B virus prevalence estimates by imputing HIV and hepatitis B infection probabilities for sample persons who lacked blood test results. This included persons who did not provide a blood sample in the quality assessment study, as well as those whose blood samples were not sufficient for laboratory analysis. The two prevalence estimates were formed as a weighted average of the actual HIV antibody test results and imputed HIV and hepatitis B infection probabilities.[2] Software for survey data analysis (SUDAAN) was used to develop the prevalence estimates and distributions, taking into account the adjusted sampling weights and complex survey design.[4] The chi-square test was used to test for statistical significance at the $P = .05$ level. Percentage of population columns in the tables reflect the distribution of demographic or behavioral characteristics of the survey participants.

Quality of Data

Of the sample person questionnaires (n = 1446), 83% had no blank items or unusable responses. The highest item nonresponse rate (6%) was for the question that asked how often a condom was used during sex with a woman in the past 12 months. A 4% item nonresponse rate was obtained for the same question asked for the time period since 1978. Since more women did not answer these questions than men, these items were probably left blank by women who felt that the items

did not apply to them. The intravenous drug use questions had a nonresponse rate of less than 1%, among the lowest observed. Fifty-seven persons (4%) had at least 18 blank items or did not answer key risk behavior questions; these persons were more likely to be from the high-risk stratum, older (35 to 54 years of age), and Hispanic. Item nonresponse data were treated as missing in the analyses.

Results

Participation Rates

Of the 1724 adults aged 18 to 54 years identified as eligible for the Dallas County Household HIV Survey, close to 90% participated; 1446 completed the questionnaire and 1374 provided a blood sample. Two sample person rates are shown in Table 1 since the special quality assessment study following the regular survey included two randomly assigned treatment groups. Half the persons were asked to complete the questionnaire only and the other half were asked to complete the questionnaire and provide a blood sample, the same procedure used in the regular survey. The weighted response rate for persons completing the questionnaire in both the regular survey and the quality assessment study was 90%, while the response rate for individuals completing a questionnaire and providing a blood sample was 84%. These response rates equal or exceed those attained in other national health surveys.[5] There were no differences in the response rates for questionnaire or blood and questionnaire among the three HIV risk strata. The lowest blood sample and questionnaire response rates were for men who reported that their ethnic group was neither Black nor Hispanic and who therefore were considered to be in the White or other ethnic group and for Hispanic women. Married individuals were less likely to provide both a blood sample and a questionnaire, and men and individuals in the oldest age group (35 to 54 years) were less likely to answer the questionnaire. If marital status is stratified by race and sex, married men and married Hispanics had significantly higher nonresponse to both the blood sample and the questionnaire.

Table 2 presents the self-reported risk behaviors by demographic categories. Overall, an estimated 8% of men aged 18 to 54 years in Dallas County reported that they engaged in male-to-male sex or bisexual activity since 1978. Receptive anal intercourse was reported by almost 5% of the men and 20% of the women. The 25- to 35-year age group, men, and not married participants were more likely to report HIV risk behaviors.

The distribution of selected health conditions and behaviors that may be correlated with HIV infection are presented in Table 3. These data, in addition to providing estimates of selected correlates of risk, also provide some indication of whether persons at risk for HIV infection participated in the survey. The rate of reported gonorrhea in the high-risk stratum was 1.7 times that reported by persons in the medium- or low-risk stratum. There was no difference between the medium- and low-risk strata for most of the correlates of risk except for reporting ever having had an HIV antibody test. Thirteen percent of the men and 8% of the women reported having been told by a doctor that they had gonorrhea. A significant racial difference was observed: 22% of Black participants reported a diagnosis of gonorrhea, compared with 9% of Hispanics and 8% of Whites. When data for gonorrhea, syphilis, and genital herpes were combined (any sexually transmitted disease), the same racial/ethnic pattern was observed as well as the higher rate in the high-risk stratum. Approximately one out of seven persons reported having previously been tested for HIV. The level of testing for persons in the high- and medium-risk strata was twice that for persons in the low-risk stratum. Twelve percent of survey participants reported "usually or every time" using a condom during sex with a man. These data reflect condom use for heterosexual women and

for men reporting male-to-male sex. There was no difference in the reporting of this behavior across risk strata.

Relationship of HIV Status with Self-Reported Risk Behaviors

The overall weighted prevalence of HIV was 0.4% and of hepatitis B virus was 7.3% (Table 4). Both virus estimates in the high-risk stratum were significantly higher than those in the low-risk stratum. Regarding HIV prevalence alone, no differences were seen between ethnic and racial subgroups. Patterns seen across the other demographic variables are consistent with known patterns of HIV infection.[6] HIV prevalence was significantly higher among men and among individuals who reported that they were not married. Finally, the highest HIV prevalence among the three age groups was for the 25- to 34-year group.

The prevalence of hepatitis B virus was also consistent with known patterns of infection.[7] There was no difference in estimates between men and women, and no association with marital status. Prevalence was significantly higher among persons in the two older age groups than among persons aged 18 to 24, while Hispanics had significantly lower hepatitis B virus estimates than other racial and ethnic subgroups.

A strong relationship was observed between the HIV status of the participants and the self-reported risk behavior data. Of the 15 sample persons who were HIV positive, all 13 men and 1 woman reported at least one behavior known to increase the risk of HIV infection. The second HIV-positive woman reported only five to nine heterosexual partners since 1978 as a potential risk factor. All 15 HIV-positive individuals were in the high- and medium-risk strata. Overall, 73% of the 120 individuals who were positive for hepatitis B virus reported one or more risk behaviors associated with HIV infection or some correlate of risk.

HIV prevalence estimates by key risk behaviors and correlates of risk are presented in Table 5. Among men who reported male-to-male sex, there was a positive relationship between the number of sex partners and the prevalence of both HIV and hepatitis B virus infection. Among men who reported 10 or more male partners, the estimated prevalence of HIV infection was almost 23% and the prevalence of hepatitis B virus was even higher (62%). Intravenous drug use was associated with a significant increase of hepatitis B virus but not of HIV in this

population. Although only 4.5% of the men reported engaging in receptive anal intercourse, 14% of these individuals were infected with HIV. Twenty percent of the women reported engaging in receptive anal intercourse, with Black women reporting a significantly lower rate of this behavior. Although this behavior was not associated with an increase in HIV infection in these women, it was associated with an increase in hepatitis B virus infection. Women reporting this behavior had twice the prevalence and men had four times the prevalence of hepatitis B virus compared with the total population.

Table 6 presents HIV and hepatitis B prevalence estimates by correlates of risk. Condom use appears to be a good predictor of both infections in men; no significant association was seen for women. An equal percentage of men and women (15%) reported ever having been tested for HIV antibody. Men who reported prior HIV testing had a higher prevalence of HIV infection than all men. Serologic evidence of hepatitis B virus infection was strongly correlated with elevated HIV infection in men.

Discussion

A survey based on a probability sample of US households had been suggested as a method to determine the number of persons infected with HIV.[8] To test the feasibility of such a survey, the NCHS conducted pilot studies at two sites through a contract with the Research Triangle Institute. This report summarizes the second field test, which was conducted in Dallas County, Texas, from September through December 1989. The response rates achieved in the Dallas survey equal or exceed those in other national health surveys.[5]

The level of risk reporting among sample persons positive for both viruses indicate that persons who engage in risk behaviors for HIV and hepatitis B virus infection will report these behaviors in a self-administered anonymous questionnaire. However, the extent of underreporting of these risk behaviors cannot be readily determined because there are no comparable studies for Dallas County, nor are there established norms in the general population. Nevertheless, the risk behaviors reported do provide information for targeting public health messages in Dallas County to prevent HIV transmission.

In particular, the one risk behavior with an unusually high level of reporting, receptive anal intercourse, should be more explicitly addressed in educational messages to the general public. Although 12.6% of the sample persons selected for the survey reported engaging in receptive anal intercourse, this risk behavior was much higher in women (20.4%). This is a higher percentage than is usually reported for this behavior in the US population.[9] Stratifying by race indicated that women who were in the non-Hispanic White/other ethnic group were one-and-a-half times more likely than Hispanic women and almost three times more likely than Black women to report this behavior. This risk behavior, although not associated with HIV infection in women at the time of the survey, does place these women at increased risk of infection as the transmission of the virus moves to the heterosexual population. This potential risk is demonstrated by the twofold higher hepatitis B virus prevalence in women in the non-Hispanic White/other ethnic group who reported this behavior compared with the total population. Thus, these women in Dallas County need to be especially targeted for messages on the risk of unprotected receptive anal sex.

Overall, 12.4% of the sample (men and women) who reported having sex with a man used condoms. This estimate is similar to other population-based surveys in the United States regardless of reporting of AIDS-related risk factors.[10]

Ten percent of the population reported having been diagnosed with gonorrhea. This reported rate in the Dallas County population is higher than that reported to the CDC.[11] In 1990, the total incidence rate of gonorrhea in the United States was 266 6 per 100 000 population (0.27%). If one accumulated reported cases between 1978 and 1989 (the time frame asked in the Dallas survey), the reported rate in the United States would

[b]Women and men reporting male-to-male sex and "usually or every time" using a condom.
[c]Gonorrhea, syphilis, or genital herpes.

be 5.0%.[12] However, it is well accepted that there is considerable underreporting of gonorrhea cases to the CDC, which these data may further substantiate. A recent overview on gonococcal infections in the United States estimates that the reported cases represent half the actual infections.[13] In addition, the male-to-female ratio in Dallas (1.7:1) is similar to that for the total United States (1.5:1).[11] If these assumptions of national reporting are correct, the 10% prevalence of self-reported gonorrhea is in the range expected.

The overall prevalence of HIV infection among the Dallas County household population was 0.4%. The prevalence of infection was significantly higher in men and in unmarried participants. There was also a strong relationship between self-reported risk behavior and HIV and hepatitis B virus prevalence; however, there was no difference between the medium- and low-risk strata for most of the correlates of risk except for reporting ever having had an HIV antibody test. The risk strata were developed using summary statistics obtained from the Dallas County Health Department surveillance programs. Population segments were classified as high, medium, or low, based on their ranking from high to low on either a rate or relative number of reportable conditions (AIDS, syphilis, hepatitis B, etc.). These summary health statistics were useful in separating the highest risk areas for sampling but less useful for differentiating moderate- from low-risk areas.

The patterns of prevalence of HIV infection across demographic variables are consistent with known patterns of HIV infection.[8,14-16] HIV prevalence was significantly higher among men than among women, as well as among individuals who reported that they were not married compared with those who reported that they were married. Finally, the highest prevalence among the three age groups was in the 25- to 34-year group. The patterns of prevalence by key risk factors were also consistent with known HIV risk behaviors.[6] Increased numbers of male-to-male sexual partners and the practice of receptive anal intercourse among men increased the prevalence of infection. Condom use during sex with a man was associated with an increase in HIV and hepatitis B virus prevalence in men, perhaps because men who knew they were infected or at risk for infection used condoms more often to protect their partners. The prevalence of hepatitis B across demographic variables was also consistent with known patterns.[7]

The strong correlation of risk factors with HIV and hepatitis B infection support the assumption that sample people are willing to report risk behavior. Although analysis of the epidemiology of these infections does not provide evidence that all high-risk individuals participated in the Dallas survey, it does suggest that those who participate in high-risk behavior were included in the survey and were willing to report this behavior. Further, the strong correlation between risk behavior reporting and HIV status among blood and questionnaire respondents provided the basis for predicting the HIV status of persons who did not provide a blood sample.

These results demonstrate that it is technically feasible to conduct a national household HIV survey, as demonstrated by the success of using phlebotomist-interviewer teams to collect blood samples and self-reported risk behavior data. However, despite the success in fielding the study and evidence that individuals who engage in high-risk behavior would participate in the survey, the inability to directly estimate nonresponse bias in the HIV prevalence estimate became an overriding concern. Because of this concern, there was no clear consensus on the scientific merit of a national survey when the CDC asked a number of outside public health, epidemiological, and survey experts to review and comment on the Dallas County HIV survey plan and findings. Therefore, the director of the NCHS recommended to the director of the CDC that a national survey not be done at the present time.[17]

In spite of this, however, the risk behavior data reported in this survey from a representative sample of Dallas County provides both a basis for community education/prevention programs to prevent the transmission of HIV infection and a useful comparison for similar surveys conducted in other counties in the future. □

Self-Reports of HIV Risk Factors by Patients at a Sexually Transmitted Disease Clinic: Audio vs Written Questionnaires

Bradley O. Boekeloo, PhD, ScM, Laura Schiavo, BA, David L. Rabin, MD, MPH, Richard T. Conlon, MPA, Carol S. Jordan, MPH, BSN, and Diane J. Mundt, PhD

ABSTRACT

Objectives. The purpose of this study was to determine how the method of assessment affects patient report of human immunodeficiency virus (HIV) risks.

Methods. Patients at a sexually transmitted disease clinic randomly received either a written self-administered questionnaire or an audio self-administered questionnaire delivered by cassette player and headset. These questionnaires were followed by face-to-face interviews.

Results. Audio questionnaires had fewer missing responses than written questionnaires. Audio questionnaires also identified more unprotected vaginal intercourse and sexual partners suspected or known to have HIV infection or acquired immunodeficiency syndrome than did written questionnaires. Although both the audio and written questionnaires identified more risks than the face-to-face interviews, the difference in the mean number of reported risks between the audio questionnaires and the face-to-face interviews was greater than that between the written questionnaires and the face-to-face interviews.

Conclusions. Audio questionnaires may obtain more complete data and identify more HIV risk than written questionnaires. Research is warranted about whether audio questionnaires overcome barriers to the completion and accuracy of HIV risk surveys. This study emphasizes the need to elucidate the relative strengths and weaknesses of written questionnaires, audio questionnaires, and face-to-face interviews for HIV risk assessment. (*Am J Public Health.* 1994;84: 754–760)

Introduction

Reliable and valid human immunodeficiency virus (HIV) risk assessment is integral for behavioral research, effective risk reduction counseling as part of clinical practice, and safe blood donation. Measurement error in HIV risk assessment can bias rate estimates of high-risk behaviors, leading to misinterpretation of research findings.[1] In clinical practice such an error can lead to undetected patient risk, resulting in missed opportunities for HIV diagnostic testing and risk reduction counseling or mislabeling of individuals as high or low risk.[2–4] As part of blood donation such an error can weaken efforts to protect the blood supply from HIV contamination.[5]

For most HIV risk factors, which include specific risky sexual and drug behaviors, self-report is typically the only acceptable method of assessment. Both face-to-face interviews[3,6–10] and self-administered questionnaires[1,2,4,11] are common methods of assessing HIV risk factors. There is evidence, however, that face-to-face interviews may have greater measurement error than self-administered questionnaires when obtaining sensitive information like sexual and drug use behaviors,[12] although neither method has been established as superior. Concern that interviews do not accurately obtain sensitive information and that paper-and-pencil self-administered questionnaires (written questionnaires) are difficult for some individuals to read and complete has led to research on computer-assisted self-administered risk assessment methods.[5]

A self-administered questionnaire that is administered by audiocassette player and headset (audio questionnaire) potentially overcomes some of the sources of measurement error associated with face-to-face interview and a typical written questionnaire. Also, an audio questionnaire is less expensive and more adaptable for use by providers in private offices than a computer-assisted assessment. Compared with the written questionnaire, the audio questionnaire might be more likely to hold respondent attention and alleviate reading problems. It might be more confidential than a written questionnaire in a nonprivate administration setting if only response options and no questions appear on the response form. Compared with the face-to-face interview, the audio questionnaire might be perceived as less threatening when behaviors of a sensitive nature are assessed. On the other hand, although the tape can be rewound and the questions reviewed, the pace of the audio questionnaire may be frustrating.

Because the primary problem in HIV risk assessment is underreporting rather than overreporting,[5] an assessment method that identifies more HIV risks than currently accepted methods is needed. Therefore, the major objective of this study was to determine whether an

audio questionnaire identifies more HIV risks than a written questionnaire in a sexually transmitted disease clinic population. The study design further allows preliminary examination of whether the two questionnaire methods identify more risk than follow-up face-to-face interviews.

Methods

The site of this study was a public sexually transmitted disease clinic in a Maryland suburb of Washington, DC. Patients 16 years of age or older who could independently complete a brief clinic registration form that asked for basic demographic information were eligible for the study. Independent completion of the registration form was used as a screen for reading and comprehension ability. Of 1017 clinic patients seen during the 6-month study period, 934 were eligible, 22 were previously enrolled repeat attenders, and 60 were ineligible. Of those who were ineligible, 82% could not independently complete the registration form because they could not understand or read English, 10% were incapable of independently completing the registration form for other reasons such as inebriation, and 8% were under 16 years of age.

The research interviewer always recruited the most recently registered eligible sexually transmitted disease clinic patient for risk assessment, skipping other patients so as not to disrupt clinic flow. Of 328 sexually transmitted disease clinic patients asked to participate in this study, 93% agreed. Patients signed consent forms before study participation and were told that information was being collected for study purposes only. Predetermined code numbers, not names, appeared on questionnaires so that the questionnaires could be matched with the face-to-face interviews. Patients were randomly assigned to receive either the written or audio questionnaire (Figure 1). After the questionnaire was administered to patients, the interview was administered. The questionnaire and interview were conducted privately, one participant at a time.

Questions to assess HIV risk were developed from model questionnaires used in previous research and included patient characteristics, sexually transmitted disease history during the past year, age at onset of sexual behavior, needle sharing ever in the past, and specific sexual, drug, and alcohol behaviors during the past 3 months. A written questionnaire was developed from the questions (Appendix). The written questionnaire was then read verbatim by a Black sexually transmitted disease counselor to provide an audiocassette for use with a headset and audiocassette player. A response form with only question numbers and response options was developed, and this form along with the audiocassette player and headset composed the audio questionnaire. The written and audio questionnaires were tested with four focus groups of volunteer sexually transmitted disease clinic patients: one group each of Black males, Black females, non-Black males, and non-Black females. Based on results from the focus groups, several wording changes were made, such as changing "sexual intercourse" to "sex" when vaginal, oral, and anal intercourse were being discussed because for many participants, "sex" connoted all intercourse and "sexual intercourse" connoted only vaginal intercourse. Short explanatory statements were added preceding questions on prostitution, alcohol use, drug use, and needle sharing because focus group participants thought that unless the relevance of these questions was explained to them, they would hesitate to answer the questions. Also, music was deleted from the audiocassette and a local Black female radio celebrity was chosen as a reader for the final audiocassette in response to preferences of the focus group participants. Revised questionnaires were then pilot-tested with sexually transmitted disease clinic patients before initiation of the study.

The survey questions were written at a seventh-grade reading level as confirmed by the Fry index,[13] whereas the survey instructions tested at at least a high school reading level. Scaled responses and skip patterns added to the difficulty of some questions. A 30-year-old Black male, an experienced counselor in the sexually transmitted disease clinic, administered both the questionnaires and the interviews. Although he was not blinded to the study group of the patient, the interviewer did not review completed questionnaires and was never part of discussions about research questions and hypotheses. Using a blank copy of the written questionnaire as a guide and response form, the counselor asked patients the HIV risk questions using whatever wording and approach he felt would elicit the most reliable and valid information. The mean length of the interviews was essentially the same in the written-questionnaire (mean = 5.58 minutes, SD = 2.68 minutes) and audio-questionnaire (mean = 5.59 minutes, SD = 2.83 minutes) study groups ($P = .98$). The interviewer estimated that the written questionnaire also took an average of 6 minutes to complete. The audio questionnaire took 14 minutes to complete if the tape was not stopped or rewound.

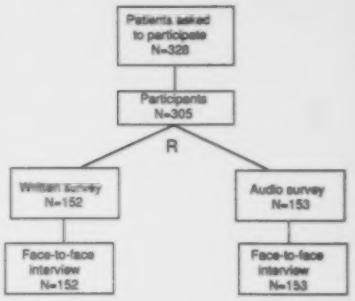

FIGURE 1—Study design.

For the purposes of this study, all 16 study variables were dichotomized and coded as "risk identified" vs "risk unidentified." Hence, categorical and continuous variables were simplified to two categories (i.e., sometimes, often, or always used nonprescription drugs to get high before or during sex vs never used nonprescription drugs to get high before or during sex). "Risk unidentified" was either a response indicating no risk or a missing response on that item. Missing responses were not excluded from the analyses because the mean percentage of missing responses across 16 items varied by risk assessment method. Hence, excluding missing responses introduced sample bias when comparisons were made between study groups. Also, including missing responses in the analysis appropriately attributed practical importance to missing data and eliminated the possibility of biasing groups with missing data toward risk identification. The approach allowed missing cases to be used in the analyses and allowed comparison of the number of identified risk factors by risk assessment method.

The chi-square test was used to compare the proportions of subjects reporting risk factors in the written and audio study groups. Student's t test was used to compare the mean number of risk factors reported in the written and audio study groups. McNemar's test for paired comparisons was used to compare propor-

tions of subjects reporting risk factors on the questionnaires and interviews. Paired *t* tests were used to compare the mean number of risk factors reported on the questionnaires and interviews. Repeated-measures analysis of variance (ANOVA) was used to compare the mean number of risk factors identified in the written and audio questionnaires while controlling for interview responses. Multiple regression was used to determine whether patient characteristics were independently associated with reporting risk factors in either the questionnaire or the interview, but not in both these methods. Statistical significance was considered to be $P \leq .05$ except where otherwise indicated.

Results

The two study groups had similar demographic profiles (Table 1). The study population was 40% female and 73% Black, with a mean age of 25 years (SD = 6.37 years). Over half (56%) of study participants had more than a high school education.

The number of missing responses for each risk factor is shown in Table 2. The mean percentage of missing responses across 16 items varied by risk assessment method: 6.4 for the written questionnaires, 3.0 for the audio questionnaires, and 0 for the interviews. The number of missing responses was greater for the written questionnaires (mean = 1.01, SD = 1.44) than for the audio questionnaires (mean = 0.48, SD = 0.72) ($P \leq .0001$). Most patients who skipped a risk factor item in the questionnaire did *not* identify risk on that risk factor in the interview (87% of the missing responses in the written questionnaire and 92% in the audio questionnaire corresponded to no identified risk in the interview).

There were no differences in the number of risk factors reported in the written-questionnaire study group (mean = 3.43, SD = 2.03) compared with the audio-questionnaire study group (mean = 3.65, SD = 2.05) ($P = .35$; Table 3). However, responses to 2 of the 16 individual risk factor items differed between the written and audio questionnaires ($P < .05$): more patients in the audio study group than in the written study group reported having had a sexual partner who was known or suspected to be HIV-infected and having had unprotected vaginal intercourse with a nonsteady partner.

The interview responses of the written- and audio-questionnaire study groups to 16 individual risk factor items were compared to determine whether the study groups had similar risk profiles (Table 3). Two differences were detected: in the interviews, the written study group reported a history of sexually transmitted disease and having had a one-night stand more often than did the audio study group. Overall, the number of reported risk factors in the interviews was not different between the written (mean = 2.97, SD = 1.77) and audio (mean = 2.68, SD = 1.86) study groups ($P = .16$).

The percentages of discordant responses between the written questionnaires and the interviews and between the audio questionnaires and the interviews were determined for each risk factor (Table 4). The number of risk factors identified in the audio questionnaire and not in the interview (mean = 1.27,

Note. NS = not significant (chi-square *P* value of > .10).
[a]Not significant by Fisher's Exact Test.

SD = 1.16) was significantly greater than the number identified in the written questionnaire and not in the interview (mean = 0.99, SD = 1.16) ($P \leq .04$).

Paired comparisons of patient-reported risk factors between the questionnaire and the subsequent interview revealed differences. The number of risk factors reported by patients first in the written questionnaire (mean = 3.43, SD = 2.03) and then in the interview (mean = 2.97, SD = 1.77) differed significantly ($P \leq .0001$) (Table 4). Responses to 4 of 16 individual risk factor items compared between the written questionnaire and the interview were different: more patients reported in the written questionnaire that they used alcohol with sex ($P \leq .05$), had unprotected vaginal intercourse with a nonsteady partner ($P \leq .01$), had unprotectd receptive anal intercourse with a steady partner ($P \leq .001$), and had unprotected receptive anal intercourse with a nonsteady partner ($P \leq .05$).

The number of risk factors reported by patients first in the audio questionnaire (mean = 3.65, SD = 2.05) and then in the interview (mean = 2.68, SD = 1.86) also differed significantly ($P \leq .0001$). Responses to 6 of 16 individual items compared between the audio questionnaire and the interview were different: more patients reported in the audio questionnaire that they had a history of sexually transmitted disease ($P \leq .05$), had sex with someone who was known or suspected to be HIV-infected ($P \leq .05$), used alcohol with sex ($P \leq .001$), had unprotected vaginal intercourse with a nonsteady partner ($P \leq .001$), had unprotected anal intercourse with a steady partner ($P \leq .001$), and had unprotected anal intercourse with a nonsteady partner ($P \leq .001$). A repeated-measures ANOVA indicated that the difference between the mean numbers of risk factors reported in the audio questionnaires and in the interviews was greater than that between the mean numbers reported in the written questionnaires and in the interviews (mean audio = 3.65 ± 2.05; mean post-audio interview = 2.68 ± 1.86; mean written = 3.43 ± 2.03; mean post-written interview = 2.97 ± 1.77) ($P = .001$).

The number of discordant responses in which risk was identified in the questionnaire and not in the interview was not associated with patient characteristics including study group, age, race, gender, level of education, or age at first intercourse in multiple regression analysis. The number of discordant responses in which risk was identified in the interview and not in the questionnaire was independently, but weakly, associated with being in the written-questionnaire study group (standardized $\beta = -0.15$, $P \leq .008$), having less education (standardized $\beta = -0.18$, $P \leq .003$), and being male (standardized $\beta = -0.14$, $P \leq .01$).

Conclusions

This study suggests that an audio self-administered questionnaire has advantages over a written self-administered questionnaire for assessing patient HIV risk. This study also raises doubts that a face-to-face interview by an experienced interviewer is the optimal method for HIV risk assessment of all patients.

There were more missing responses in the written than in the audio questionnaires. Matching of responses between the written questionnaire and the interview revealed that many patients who skipped a risk factor item in the written questionnaire reported in the interview that they did not have that risk factor—except for responses about a history of sexually transmitted disease and unpro-

tected vaginal intercourse with a steady partner. It is unclear why a history of sexually transmitted disease was frequently unreported in the written questionnaire but was reported in the interview. For other questions, comparison of matched interview responses with missing responses in the written questionnaire suggested that patients sometimes skipped questions in the written questionnaire when they believed the questions did not apply to them because they usually did not report risk in the interview. The readability of complex questions may have been a problem for some patients. Compared with the written questionnaire, the audio questionnaire resulted in less skipping, perhaps because readability was less of a problem and attention to instructions requesting responses to all questions was greater when the audio method was used.

Although both types of questionnaires elicited the same number of reported risk factors when administered to randomized groups of patients, analysis of individual risk factor items suggested that the audio questionnaire identified more risk than the written questionnaire. On two individual risk factors—having had a sexual partner who was known or suspected to be HIV-infected and unprotected vaginal intercourse with nonsteady partners—significantly more patients reported risk in the audio questionnaire than in the written questionnaire. Interviews of these two groups demonstrated no differences on these risk factors. Furthermore, when discordant responses between the questionnaires and the interviews were analyzed, the audio questionnaires identified more risk factors than did the written questionnaires.

The educational level of this study population of patients at a sexually transmitted disease clinic was fairly high, indicating a high level of literacy. Also, the questionnaires were completed in private rather than in waiting rooms or nonprivate rooms in this study. These factors may have diminished the differences in reported risk between the written and audio questionnaires. Future research should determine whether the audio questionnaire is more effective in eliciting and identifying risk than the written questionnaire when administered to a population with a lower level of education and in waiting rooms rather than in private rooms.

More risk factors were identified in both the written and audio questionnaires than in the interviews. When rates of individual risk factors were compared among methods, more alcohol use with sex, more unprotected vaginal intercourse with nonsteady partners, and more anal intercourse with both steady and nonsteady partners were identified in both the written and audio questionnaires compared with the interviews. History of sexually transmitted disease and having had a partner with AIDS were also more often identified in the audio questionnaire than in the interview. These results indicated that both questionnaires identified more risk than the interview but that the audio questionnaire identified more risk compared with the interview than did the written questionnaire.

There were several possible explanations for the differences in responses observed between the questionnaires (written and audio) and the interviews. The order of administration of risk assessment methods (questionnaire followed by interview) may have influenced risk factor reporting. Self-administered questionnaires could have "primed" patients to conceal risky behaviors in the interviews, although it is just as plausible that they could have primed patients to reveal risky behaviors in the interviews. Face-to-face interviews might have been rushed due to patient impatience or interviewer concern about time and therefore might have been less thorough than the questionnaires. The interviews did take less time than the questionnaires. Nevertheless, concern over time would have been greater for postaudio interviews than for postwritten interviews due to the longer length of the audio questionnaire. Yet the interviews were the same length in both the written and audio study groups. Finally, the differences observed in risk reporting between the questionnaires and the interviews may have been at least in part attributable to the greater anonymity provided by the questionnaires.

A likely explanation for the differences in responses between the questionnaires and the interviews was that the experienced sexually transmitted disease clinic interviewer did not obtain accurate information for all risk factors. That interviewers, including physicians, have difficulty discussing patients' specific sexual practices has been observed in previous studies.[14,15] Although the interviewer was allowed to rephrase questions to encourage more revelation of risk and to reduce repetitiveness with the prior question-

naire, this rephrasing may have resulted in less direct questioning about sensitive behaviors, thus limiting patient responses. Also, patients may have been less revealing in the interview than in the questionnaires because they were uncomfortable with the interviewer.

We attempted to characterize patients who identified risk in the questionnaires but not in the interviews, and vice versa, to provide insight as to which types of individuals revealed more risk in which type of assessment. Significant findings were that the number of discordant responses in which risk was identified in the interviews but not in the questionnaires was weakly correlated with being in the written-questionnaire group, having less education, and being male. These findings suggest that the interviews identified more risk information after the written questionnaires than after the audio questionnaires, further confirming that audio questionnaires are more thorough than written questionnaires. Individuals with less education were probably less able to understand and complete written questionnaires compared with audio questionnaires. Finally, male more than female patients were more likely to reveal risk, and perhaps even to overreport risk, in the interviews compared with the questionnaires. That the interviewer was male may have contributed to this finding because match of the interviewer and patient on gender may affect interview responses.

A limitation of this study is that there is no way of determining which method of risk assessment provided the most valid responses. Because it seems more likely that patients would underreport rather than overreport their risky sexual practices to avoid embarrassment or disapproval, we assume that the method in which patients reported the greatest number of risk factors is the more valid. It was possible that patients erroneously reported risk factors because they misunderstood particular questions, especially in the written questionnaire, which depended on high literacy. For clinical purposes, the method that errs toward overreporting of risk might be preferred to one that errs toward underreporting of risk because diagnostic and educational follow-up is usually provided only for those patients for whom risk is identified. Overreporting would also be preferred in screening for blood donation.

Findings of this study support previous research suggesting that self-administered questionnaires may reduce barriers to HIV risk factor reporting found in face-to-face interviews,[12] although reading and comprehension difficulties can decrease the usefulness of questionnaires. Compared with a written questionnaire, an audio questionnaire has the potential advantages of being confidential in a waiting room, requiring minimal reading ability, and encouraging attention to every instruction, question, and question response. This study suggests that an audio questionnaire obtains more complete data and identifies more risk factors than a written questionnaire. Based on the findings of this study, further research is warranted as to whether assessing HIV risk with an audio questionnaire can overcome reading, attitudinal, and situational barriers to survey completion and accuracy. Also, this study emphasizes the need to further elucidate the relative strengths and weaknesses of written and audio questionnaires and interviews for HIV risk assessment. □

APPENDIX—HIV Risk Assessment Questions

1. In the *past 12 months,* how many times have you been diagnosed with an STD or VD?
2. Have you ever had sex with someone who you know, or suspected, had a positive blood test for the AIDS virus?
3. *In the past 3 months,* with about how many different men did you have sex?
4. *In the past 3 months,* with about how many different women did you have sex?
5. At any time *in the past 3 months,* did you have sex with a man who had sex with other men?
6. *In the past 3 months,* have you had a "one night stand" with anyone?
7. At any time *in the past 3 months* did you give or receive money or drugs for sex with a boy or man?
8. At any time *in the past 3 months* did you give or receive money or drugs for sex with a girl or woman?
9. *In the past 3 months,* about how often did you use alcohol including liquor, beer, or wine of any type before or during sex?
10. *In the past 3 months,* about how often did you use nonprescription drugs to get high before or during sex?
11. *In the past 3 months,* have you had sex with anyone who injected drugs with needles?
12. Have you ever used a needle or syringe *after* someone else used it or may have used it?

The next set of questions ask about your condom use with a *steady partner*—your boyfriend, girlfriend, or spouse only. If you had sex with other people, these questions do not pertain to them. In the *past 3 months:*

(For men and women)

13. About how often was a condom used when your partner put his penis in your rectum?

(For women)

14. About how often was a condom used when your partner put his penis in your vagina?

(For men)

15. About how often was a condom used when you put your penis in your partner's vagina?
16. About how often was a condom used when you put your penis in your partner's (male or female) rectum?

The next set of questions ask about your condom use with a *nonsteady partner(s)*—people other than your boyfriend, girlfriend, or spouse. In the *past 3 months:*

(For men and women)

17. About how often was a condom used when a man put his penis in your rectum?

(For women)

18. About how often was a condom used when a man put his penis in your vagina?

(For men)

19. About how often was a condom used when you put your penis in your partner's vagina?
20. About how often was a condom used when you put your penis in your partner's (male or female) rectum?

HIV Vaccine Trials: Will Intravenous Drug Users Enroll?

Kathleen Meyers, MS, David S. Metzger, PhD, Helen Navaline, BA, George E. Woody, MD, and A. Thomas McLellan, PhD

ABSTRACT

Objectives. The purpose of this study was to assess the willingness of intravenous drug users to participate in a preventive human immunodeficiency virus (HIV) vaccine efficacy trial.

Methods. Of the 347 intravenous drug users in methadone treatment who were approached for participation, 257 completed a battery of self-administered questionnaires assessing risk behaviors, interest in vaccine trials, and other vaccine-related information. Data from 16 known seropositives and 1 inconsistent responder were dropped from analyses (n = 240).

Results. Fifty-two percent of the subjects expressed a willingness to be one of the first individuals to participate in a preventive HIV vaccine efficacy trial. Subjects who had recently shared needles or works and subjects who trusted the government to ensure vaccine safety were both twice as likely to report interest in participation. Twenty-two percent of subjects reported that they would increase needle sharing if vaccinated. Thirty percent did not know what a vaccine was.

Conclusions. These findings suggest that some in-treatment intravenous drug users would volunteer for a preventive HIV vaccine efficacy trial. Education and counseling will be required to ensure that subjects fully understand the trial's purposes, methods, risks and benefits. (*Am J Public Health.* 1994;84:761–766)

Introduction

Despite impressive risk reduction resulting from behavioral and educational interventions launched to halt the spread of human immunodeficiency virus (HIV) infection, sizable portions of both the homosexual/bisexual and intravenous drug using populations continue to engage in, or have relapsed into, behaviors that place them at risk of acquiring the virus.[1–4] Of parallel concern is the apparent absence of meaningful risk change among the large number of individuals who do not view themselves at particular risk (e.g., adolescents, adult heterosexuals).[5–7] In fact, the acquired immunodeficiency syndrome (AIDS) has emerged as a leading cause of death among US adults less than 45 years of age and US children 1 to 5 years old.[8] Thus, there is an urgent need for the development and testing of preventive HIV vaccines.

Currently, a number of experimental HIV vaccines have entered phase I and II clinical trials.[9–11] As this work progresses and preparation for phase III trials begins, epidemiological, ethical, and public health considerations are being cooperatively addressed by national and international groups.[12–16] At the same time, a critical practical question is the willingness of at-risk individuals to participate in the upcoming vaccine trials. To date, little work has been undertaken to delineate the issues associated with recruitment and retention of subjects for HIV vaccine trials.

An initial step in testing the efficacy of candidate HIV vaccines is gaining access to populations at risk of HIV infection. Under a cooperative initiative among the National Institute of Allergy and Infectious Diseases (NIAID), the National Institute on Drug Abuse (NIDA), and the Centers for Disease Control, homosexual/bisexual men, intravenous drug users, and other at-risk individuals are being targeted for participation in these efficacy trials.[12] The active participation of gay men in helping to formulate the HIV research and treatment agenda suggests that this community recognizes the importance of vaccine trials, although their willingness to be participants awaits empirical examination. There is less certainty regarding the willingness of intravenous drug users to participate in vaccine trials, since they are not well organized and tend to be a disenfranchised group.[17] Consequently, it is important to develop some indication of intravenous drug users' willingness to volunteer for such a study. Most important is determination of whether seronegative subjects who are at the greatest risk of infection will be willing to participate. These assessments will have direct bearing on the estimate of sample sizes needed for vaccine trials. For example, if those at greatest risk for seroconversion are unwilling to enroll, sample sizes for vaccine trials will need to be much larger than if such individuals are willing to participate.

With support from the NIAID/NIDA vaccine preparedness initiative, we had the unique opportunity to rapidly collect preliminary data on the willingness of intravenous drug users to participate in efficacy trials for HIV preventive vaccines.

This paper was accepted August 3, 1993.

As part of recruitment procedures for a new cohort of subjects participating in a longitudinal study of risk behaviors and HIV infection among intravenous drug users in Philadelphia,[18] methadone patients were questioned about their willingness to participate in early vaccine trials. Subjects were also briefly questioned regarding their knowledge of vaccines, trust in government, and other issues considered important in gaining a preliminary understanding of the factors associated with trial participation. Methadone patients not only represent the target population of intravenous drug users in treatment but provide access to their out-of-treatment intravenous drug using associates, a group at particularly high risk. Therefore, they constitute a readily available sample from which we can gain some early insight regarding intravenous drug users' willingness to enroll in HIV vaccine trials and an important link to the out-of-treatment community.

This paper presents self-report data from a brief opinion questionnaire about these issues among 240 intravenous drug users. It explores the feasibility of recruiting such individuals for clinical vaccine trials, examines whether seronegative subjects at greatest risk of HIV infection report willingness to participate in HIV vaccine trials, and discusses issues related to their ability to provide informed consent for such trials.

Methods

Procedures

The study sample was composed of methadone maintenance patients from the Girard Methadone Program located in north-central Philadelphia. All eligible methadone patients were approached for screening as part of recruitment procedures for a longitudinal study of HIV infection and associated risk behaviors.[18] Of those screened (n = 347), 257 (74%) agreed to complete our initial assessment.

After providing informed consent, subjects completed a battery of self-administered risk assessment questionnaires in closely supervised groups of 5 to 10. Included in the battery was a one-page vaccine opinion questionnaire developed specifically for this project. Throughout questionnaire completion, research staff members were present to answer questions, assist those with reading difficulty, and screen completed questionnaires for missing data or inconsistent responses. Subjects were paid $5 for their participation.

Subjects

Of the 257 subjects who completed questionnaires, 16 reported being HIV positive and 1 provided inconsistent responses. The data from these 17 subjects were deleted from further analyses, resulting in a final sample of 240 subjects. Subjects ranged in age from 20 to 64 years, with a mean of 39.1 years (SD = 7.0). The sample was ethnically diverse (44% African American, 39% Caucasian, and 17% Latino). Seventy percent of the sample was male. The median monthly income was $246, with most subjects (80%) receiving public assistance as their primary source of income. Fifty-nine percent had a high school diploma or general equivalency diploma. The median length of time in the current methadone program was 1.5 years.

Measures

The Vaccine Opinion Questionnaire was developed for this project on the basis of input from both intravenous drug users and research staff. While the assessment battery was being developed, we asked subjects in our original cohort to comment on vaccine research and what issues might be important for participation from the perspective of potential participants. We also asked our research staff to suggest issues that should be examined. These staff members have extensive contact with intravenous drug users, and they were encouraged to report issues and concerns that existed among the intravenous drug using community in regard to vaccines, treatment, and related issues. On the basis of this information, a brief self-report questionnaire was designed to identify some of the potentially important factors associated with trial participation. The resultant questionnaire was composed of 13 statements with which the subject could either agree or disagree and 3 multiple-choice questions. The questions, which were grouped post hoc, covered HIV-related issues, vaccine histories of both the respondent and his or her children, trust in government, vaccination knowledge, potential behavioral change after participation, and willingness to participate.

Formal reliability and validity testing was not conducted because our opportunity to examine this cohort was time limited. Therefore, we took care to maximize the face validity of the items constituting the questionnaire. For example, we used simple language that would be understood by this population. We also monitored all subjects during and after administration of the questionnaire, answering questions and clarifying inconsistencies. For these reasons, we are confident of the face validity of this instrument. Obviously, the only conclusive method of testing the predictive validity of the instrument would be to correlate answers on the questionnaire with actual participation in a vaccine trial. We will complete this formal study when the opportunity arises.

The Risk Assessment Battery,[19] an instrument composed of 38 closed-ended items that cover frequency and route of administration of various substances, needle sharing and cleaning, and high-risk sexual behavior, including sexual orientation, condom use, and exchange of sex for drugs or money, was used in collecting risk-associated behavioral data. Preliminary validity data show the instrument to have good predictive validity for HIV seroconversion.[19] The Risk Assessment Project Questionnaire yielded demographic and descriptive information about the subjects' current social conditions, drug treatment, history of criminal behavior, and legal history. The entire test battery took approximately 30 minutes for most subjects to complete. A considerable body of literature now exists supporting the validity and reliability of self-report measures within this population.[20,21]

Results

Trust

As can be seen in Table 1, the subjects expressed considerable distrust in the government. Fifty-three percent of the subjects believed that the health department was not doing all that it could to stop the spread of AIDS, and 32% believed that a cure for AIDS was available but being kept from the public. Thirty-six percent endorsed the belief that HIV is a man-made virus created to get rid of "certain groups" of people. Specifically related to trust in vaccine trials, 48% of the subjects did not trust the government to ensure vaccine safety prior to trials. This is particularly troublesome for recruitment, given that safety issues emerged as the most important issue reported by respondents (42%) regarding their participation.

Vaccine Knowledge/Experience

Responses indicated that the subjects were in need of education regarding vaccines. Thirty percent of the sample

were unsure what a vaccine was, and 41% did not know that a vaccine could prevent disease acquisition. This apparent lack of knowledge existed despite high rates of vaccination for other communicable diseases: 84% reported having been vaccinated for measles, mumps, or polio, and 93% of those subjects with children (n = 192) indicated that their children had been vaccinated. A higher proportion of those who admitted not really knowing what a vaccine was than of those who reported such knowledge did not have a high school education or a general equivalency diploma (55% vs 35%; $\chi^2 = 8.3$, $df = 1, P < .005$).

TABLE 1—Subjects' Opinions Regarding Vaccines and Related Issues, by Topic Area (n = 240)

	% Agreeing or Answering Yes
Trust	
The health department is doing all it can to stop the spread of AIDS.	47
There is a cure for AIDS, but the government is keeping it from the public.	32
I trust the government to make sure that vaccines they want to test are safe before they test them on people.	52
HIV is a manmade virus that was created to get rid of certain groups of people.	36
Vaccine knowledge/experience	
A vaccine can protect you from getting a disease.	59
A vaccine does not help someone infected with a disease.	48
Getting vaccinated can be risky.	48
I am not sure what a vaccine is.	30
Have you ever received a vaccine for a disease like measles, mumps, or polio?	84
Were your children vaccinated for things like measles, mumps, or polio?	93
Behavioral impact	
If I was sure I couldn't get AIDS, I'd probably share needles more often.	22
Trial participation willingness	
I would be willing to be one of the first people to try an HIV vaccine.	52
I would be willing to try a vaccine for HIV even if there was a slim chance of getting sick from it.	39
What would be most important for you to try a vaccine for HIV if one were available?	
The vaccine was safe.	42
I would be guaranteed medical care for any problems related to the vaccine.	20
I would have the opportunity to be protected from getting HIV.	35
I would receive money for trying the vaccine.	3

Behavioral Impact

Regarding the potential impact of vaccine trial participation on high-risk behaviors, 22% of the subjects thought that they might share needles more often if they were guaranteed protection from HIV infection. This reported potential for increased risk behaviors was more common among current needle sharers (40%) than among those not sharing (17%) ($\chi^2 = 14.7$, $df = 1$, $P < .001$), but it was not more common among those who reported willingness to participate in the trials. Whether these subjects would attempt to determine their vaccination status was not examined.

Participation Willingness

Despite substantial mistrust and lack of knowledge, a slight majority (52%) of the subjects expressed a willingness to be "one of the first" individuals to participate in an HIV vaccine trial, and 39% reported that they would be trial participants even if there was a slim chance of getting sick as a result of vaccination. When subjects were questioned about the factors that would be most likely to influence their decision to enroll, safety issues emerged as most important, followed by the opportunity to be protected from HIV infection, guaranteed medical care for any vaccine-related problems, and monetary reimbursement for trial participation.

Associated Willingness Factors

To explore factors associated with willingness to participate, subjects were categorized according to their answers on that question. As can be seen in Table 2, those willing to be part of a vaccine trial were demographically similar to those who were unwilling to be part of a trial. However, willing subjects had spent significantly less time in the current methadone program ($t = 1.98$, $df = 236$, $P < .05$) and were more likely to report current health problems ($\chi^2 = 5.1$, $df = 1$, $P < .05$) than unwilling subjects. Not surprisingly, those willing to be vaccine trial participants were proportionately more likely to believe that the government would ensure vaccine safety prior to testing ($\chi^2 = 5.8$, $df = 1$, $P < .05$), although the groups were proportionately similar on other trust issues. Surprisingly, basic knowledge of vaccines, particularly being unsure of what a vaccine was and knowing that vaccines can be protective, was unrelated to participation willingness.

As stated, an important focus of this study was an exploration of whether subjects engaging in risk behaviors were willing to enroll in vaccine trials. To this end, subjects were grouped according to their risk status on HIV-associated drug behaviors (e.g., shared needles/did not share needles in the prior 6 months) and HIV-associated sexual behaviors (e.g., no or irregular condom use with two or more sexual partners in the prior 6 months). The chi-square statistic was used in conducting a univariate analysis of the proportion of willing participants within these groups.

Significantly more of those who perceived themselves as being at risk of HIV exposure than of those who did not perceive themselves as at risk reported willingness to be one of the first to try a vaccine (59% vs 41%; $\chi^2 = 7.3$, $df = 1$, $P < .01$). Similarly, willingness to try a vaccine was significantly higher among those who recently shared needles than among those who did not share needles (66% vs 48%; $\chi^2 = 6.2$, $df = 1$, $P < .01$). Willingness was also more common among those who engaged in other risky drug using behaviors such as sharing a cooker, cotton, or rinse water in the previous 6 months (62% among those who shared vs

*$P < .05$.

45% among those who did not share; $\chi^2 = 6.5, df = 1, P < .01$).

Willingness was unrelated to our measures of risky sexual behaviors: 58% vs 51% for those engaging in and those not engaging in unprotected intercourse with multiple (two or more in past 6 months) sexual partners ($\chi^2 = 0.6$, not significant* [NS]) and 63% vs 51% for those engaging in and those not engaging in sex for drugs or money in the prior 6 months ($\chi^2 = 1.9, df = 1$, NS).

Logistic regression was used to simultaneously adjust for age, sex, and race as well as the potential predictors of willingness to participate in vaccine efficacy trials: engagement in high-risk behaviors, trust in government, and vaccine knowledge. As can be seen in Table 3, subjects who shared needles or works were twice as likely to report willingness to participate in trials, as were those who reported that they trusted the government to ensure vaccine safety prior to trials. Demographic variables, sexual HIV-risk-associated behaviors, trust issues other than safety, and knowledge of vaccines were not significantly associated with reported willingness to participate in vaccine trials.

Discussion

These data from our initial questionnaire suggest that some in-treatment intravenous drug users would volunteer for HIV vaccine trials. Importantly, those in-treatment users who continued to place themselves at risk for HIV infection were significantly more likely to report that they would be one of the first to try a vaccine than those who engaged in safer behaviors. If these findings are confirmed and high-risk intravenous drug users are truly willing to enroll, the number of subjects necessary for efficacy vaccine trials could be minimized.

However, just under half of the intravenous drug users questioned expressed an unwillingness to enroll in vaccine trials. It was clear that a substantial lack of knowledge about vaccines and distrust in the government were evident among this group, and these factors will have to be addressed if participation rates are to be maximized. The data reported here suggest that mistrust of the government regarding vaccine safety is a key mediating variable in the recruitment of intravenous drug users for HIV vaccine efficacy trials. Efforts to combat this lack of trust and provide safety data should guide subject recruitment and trial imple-

mentation from the outset. In addition to doing everything possible to ensure vaccine safety, it may be helpful to select field workers who are part of the intravenous drug using community, rather than governmental officials, to recruit and engage at-risk users.

While this paper has reported on the responses of in-treatment intravenous drug users, it will also be important for HIV vaccine trials to recruit and retain out-of-treatment users. In our ongoing study of HIV infection, we have successfully used our in-treatment cohort to refer us to out-of-treatment subjects. Our findings indicate that out-of-treatment intravenous drug users engage in substantially higher levels of risk behaviors and have higher seroconversion rates than their in-treatment counterparts.[18] Both of these are important considerations for vaccine trial participation.

This study showed no significant difference in willingness to participate among the racial groups. However, since a high proportion of intravenous drug users are African Americans and Latinos, sensitivity and responsiveness to minority issues will be critical in vaccine trials. As noted by El-Sadr and Capps,[22] minority recruits may be an especially distrustful group, considering the past patterns of insensitivity during clinical trials exemplified by the legacy of the Tuskegee Syphilis Study.

One of the most important issues that will need to be addressed prior to vaccine trials is that of *informed* consent. Although knowledge of vaccines as measured here was unrelated to participation willingness, the reported lack of general knowledge regarding vaccines is alarming. Approximately one third of our subjects admitted to not really knowing what a vaccine was, and more than half did not know that there are preventive and therapeutic vaccines. Of course, it may be that this is representative of the knowledge base of nonusers from the same socioeconomic strata. Despite this apparent lack of basic knowledge, many subjects agreed to consent to trial participation without adequate comprehension of the issues. This scenario will obviously test our ability to ensure that subjects know what vaccines are and fully understand the trial (e.g., placebo-controlled issues) and its uncertainties (e.g., potential risks, efficacy uncertainties) so that they can make truly informed and knowledgeable decisions regarding enrollment. This becomes an even more important issue given the educational level of this group of subjects. Clear and concise information regarding the type of vaccine (e.g., subunit vs live vectors) to be tested in each trial, the research method (e.g., placebo-controlled study), and the consequences of participation (e.g., vaccine-induced seroconversion) will need to be provided in a way that ensures comprehension. The ability to engage subjects in an open, honest dialogue in order to dispel myths, allay fears, and candidly address the type and amount of risk the trial entails will undoubtedly influence enrollment. Included should be a frank discussion of compensation issues, in the event that subjects sustain harm, as well as the potential for discrimination after an immune response resulting from vaccination. In addition, it may be necessary to include a brief factual quiz regarding vaccine participation with a "cutoff score" as part of subject consent procedures. This may be the only definitive method of ensuring truly informed consent in future trials.

As subjects learn more of the specifics of these proposed vaccine trials, willingness will undoubtedly change, although the direction of the change is unknown. In an effort to better understand potential participation issues, we are currently using both interviews and self-report measures to assess reported willingness to participate under conditions that will approximate actual trials (e.g., randomized, placebo-controlled trials). Information delivery methods (e.g., videotapes) and the individuals who disseminate such information (e.g., other intravenous drug users, health officials) will probably vary in efficacy; this area requires study.

An important ethical consideration for recruitment is remuneration for participation. High monetary rewards offered to economically disadvantaged groups can be considered enticing to the point of coercion. Thus, it is particularly important to identify the nonmonetary issues that are most strongly associated with willingness to participate. This will help to identify factors that can attract potential participants based only on scientific and humanitarian issues. Although financial incentives are important for study compliance, they must not become the sole reason for enrollment.

Although few subjects reported the possibility of an increase in risk behaviors, the impact of vaccine trial participation on a subject's practice of risk behaviors requires further attention. Relapse into unsafe behaviors as a result of a "sense of safety" through vaccine trial participation would be problematic not only if the initial vaccines are less than 100% effective, but also in light of other consequences (e.g., hepatitis, sexually transmitted diseases). The ability of intravenous drug users to determine whether or not they received a placebo or vaccine, as well as their interest in doing so, is currently unknown and under investigation. Further exploration of other key vaccine trial issues (e.g., subjects' knowledge of placebo issues, vaccine-induced seroconversion) is an ongoing aim of our current work.

While the data reported here provide some preliminary insight into the willingness of intravenous drug users to participate in HIV vaccine efficacy trials, the only true measure of the validity of these responses will be whether those who say they will participate actually enroll in efficacy trials. We are currently in the process of assessing the degree of stability of a subject's stated participation willingness over the course of the preparedness work. If changes in willingness occur over time, we will ascertain whether any factors correspond to this fluctuation. For example, changes in willingness may be related to changes in risk behaviors. Subjects may be more likely to consider participation in vaccine efficacy trials during periods of high-risk behaviors and less likely to consider participation during safer periods. Whether this phenomenon exists at all and whether it is consistent across categories of risk behaviors will be the subject of future reports.

From these preliminary data, it is clear that the recruitment of intravenous drug users into HIV vaccine efficacy trials will require a sustained cooperative effort on the part of the vaccine and drug research and treatment communities. Together, these communities must determine appropriate incentives and develop and disseminate appropriate educational materials that can provide accurate descriptions of the study and understandable information on potential trial risks. The way in which these issues are addressed will undoubtedly form the cornerstone of recruitment efforts. As vaccine efficacy trials approach, we must quickly address the above issues and our understanding of the factors associated with enrollment if we are to recruit and engage the intravenous drug–using community. □

A Community-Based Heart Disease Intervention: Predictors of Change

Marilyn A. Winkleby, PhD, June A. Flora, PhD, and Helena C. Kraemer, PhD

ABSTRACT

Objectives. This paper presents a prospective examination of sociodemographic, psychosocial, and physiologic characteristics associated with positive change in cardiovascular disease risk factors during a 6-year multiple risk factor intervention study.

Methods. Data are presented on 221 women and 190 men (aged 25 through 74 years) who participated in four cohort surveys (1979 through 1985). A signal detection model was used to identify baseline variables that best divide the sample into subgroups on the basis of the probability of positive change in a composite risk factor score.

Results. Sixty-nine percent of the respondents showed a positive change in risk factor score during the intervention. The subgroup with the highest proportion of positive changers (83%) was composed of older adults (>55 years) with the highest perceived risk, highest health media use, and highest blood pressure and cholesterol levels. The subgroup with the lowest proportion of positive changers (42%) was the least educated, was the most likely to be Hispanic, and had the lowest health knowledge and self-efficacy scores.

Conclusions. The differing composition of subgroups who respond or do not respond to community cardiovascular disease interventions illustrates the need to develop specific interventions that target different age, socioeconomic, and cultural subgroups. (*Am J Public Health.* 1994; 84:767–772)

Introduction

The Stanford Five-City Project is a long-term field trial designed to test whether a comprehensive program of community organization and health education produces favorable changes in cardiovascular disease risk.[1] Changes in overall risk factors have been reported[2] and indicate a beneficial educational effect, especially with regard to blood pressure[3] and smoking.[4]

In this paper, we present prospective data on respondents from the two treatment cities. We identify those who showed favorable risk factor changes and compare their baseline sociodemographic, psychosocial, and physiologic characteristics with those of respondents who showed unfavorable changes. This procedure allows for the identification of subgroups who are most likely to respond to a community intervention like the Five-City Project, as well as subgroups who deserve special attention because of their lack of positive change.

Because intervention programs increasingly involve the targeting of multiple risk factors[1,5,6] and because the primary goal of community cardiovascular disease intervention studies is overall improvement in the community's health, we used a summary measure that incorporates multiple cardiovascular disease risk factors as our indicator of change. Using a signal detection model designed to develop optimal sequential rules,[7] we identified baseline health-related variables that best divide the sample into subgroups on the basis of the probability of positive change in risk factor status.

Our selected variables reflect the theoretical bases of the Project's education program: social learning theory,[8,9] the communication-persuasion model,[10] the social marketing model,[11] and the theory of reasoned action.[12] We evaluate knowledge and attitudes about cardiovascular disease that often accompany behavior change[13]; perceived self-efficacy about diet and exercise, which has been shown to be important in predicting behavior change[14]; perceived cardiovascular disease risk, which has been shown to be important in understanding how individuals change[15]; and health media use, which has been shown to be related to exposure to the Five-City Project campaign.[16]

Methods

The Five-City Project drew subjects from two treatment and two control cities in Northern California, ranging in population size from 35 000 to 145 000 residents (a fifth city was monitored for morbidity and mortality, but not for risk factor change). To assess change in risk factors, independent cross-sectional surveys of randomly selected households and repeated surveys of a cohort were conducted. All persons aged 12 through 74 years were eligible to participate and were invited to attend survey centers located in each community. Detailed descriptions of the study design and methodology have been published previously.[1,17,18]

This analysis focuses on adults aged 25 through 74 years living in the two treatment cities who participated in at least the baseline cohort survey (1979/80) and the final cohort survey (1984/85).

This paper was accepted August 3, 1993.

When these subjects also participated in either or both of the interim cohort surveys (1980/81 and 1982/83), interim data were also used. Eighty-seven percent of those who participated in the baseline and final surveys also participated in both of the interim surveys.

The Education Intervention

The 6-year education intervention targeted all residents in the treatment communities and involved a multiple risk factor strategy delivered through multiple educational channels.[19] Mass media (television and radio) programs formed a major proportion of the intervention. Print media (newspaper health columns and pamphlets) were delivered through direct mail, at work sites, and through medical care givers.[20] Special emphasis was given to designing materials for those with low literacy levels and disseminating programs to low-income Spanish-speaking populations, particularly via radio.

Outcome Variable

As an overall measure of change in cardiovascular disease risk factors, we chose change in a composite risk factor function (based on the Framingham Study) that provides an estimate of all-cause mortality risk per 1000 persons in 10 years.[21] The risk function, which is sex-specific, is a combination of cigarettes per day, total plasma cholesterol, mean diastolic blood pressure, and pulse (men only). Although we recognize that an individual's response may be specific to one component of the risk score (e.g., smoking) but not to another component (e.g., cholesterol), our objective was to select an outcome indicative of overall improvement in health. Furthermore, a single outcome variable avoids problems of collinearity and multiple-hypothesis testing. It thus provides a more powerful method of assessing the simultaneous effects of multiple risk factors than do analytic methods that become impractical when separate variables are used.

Information on variables used in the risk assessment was obtained by experienced nurses and laboratory technicians. Respondents were asked if they had smoked any cigarettes in the past week. If no cigarettes were smoked, respondents received a code of zero; if one or more cigarettes were smoked, they received a code reflecting the number of cigarettes smoked per day. Although no biochemical measures were used to validate the number of cigarettes smoked per day, previous analyses have shown a high degree of accuracy between self-reported and biochemical measures for overall smoking status.[4,22] Total plasma cholesterol was derived from nonfasting venous samples and analyzed by standard methods established by the Lipid Research Clinic Program.[23] Three blood pressure measurements were taken on the right arm with a semiautomatic recorder (Sphygmetrics SR-2 automatic blood pressure recorder) that minimizes observer bias.[17] The mean of the second and third diastolic readings were used for analyses. Resting pulse was determined by direct palpation for 1 minute.

We calculated respondents' composite risk factor functions at each survey time from the values of their risk factors at that time. (The mean baseline risk score was 3.5 [SD = 1.2].) Age was held constant for each individual at his or her baseline age, allowing for the examination of change in risk due to factors targeted by the intervention. After calculating a respondent's risk function values at each survey, we employed a random regression model to fit a unique slope for each respondent.[24] On the basis of the value of their individual slopes, individuals were divided into two groups, one representing positive changers (those with a positive slope, indicating a general improvement in risk score over the course of the surveys) and one representing negative changers (those with a negative slope, indicating a worsening of risk score).

Predictor Variables

Predictor variables used in our analysis include six baseline sociodemographic variables (age, education, marital status, ethnicity, sex, city of residence) and five baseline psychosocial variables (cardiovascular disease health knowledge, health attitudes, self-efficacy, perceived risk, and health media use).

Information on sociodemographic variables and psychosocial variables was obtained from self-reported questionnaire data. Age and education were collected as continuous variables and marital status (currently married or not currently married) and ethnicity (White, Hispanic) were collected as dichotomous variables. The 2% of the sample who were Asian and the 2% who were African American were excluded from this analysis. Education was selected as the measure of socioeconomic status because education is available for all individuals regardless of employment status, has high reliability and validity, is generally stable after early adulthood,[25,26] and has recently been shown to have a stronger association with cardiovascular disease risk factors than income or occupation.[27,28]

Nine psychosocial predictor variables were initially selected for analyses—these were reduced to five by means of a principal components analysis to reduce collinearity. Health knowledge was measured on a summative scale of 17 items about cardiovascular disease risk factors (Cronbach's $\alpha = .66$). Health attitudes were measured on a summative scale encompassing four dimensions—8 physical activity items, 7 weight items, 10 nutrition items, and 10 stress management items ($\alpha = .83$). Self-efficacy was based on 13 diet and exercise items ($\alpha = .79$), and perceived cardiovascular disease risk was measured by one item (scale of 1 to 7). Health media use, which assesses the frequency with which health information is obtained from newspapers, magazines, and pamphlets sent in the mail, was based on four items and was standardized to a mean of 0 and a standard deviation of 1 ($\alpha = .70$). Higher scores reflect higher health knowledge, more positive health attitudes, higher self-efficacy, greater perceived risk, and higher health media use.

Statistical Model

A multiple logistic regression model including interaction terms is a common analytic method for identifying characteristics of respondents who show favorable risk factor changes compared with those who do not. We used this method initially, but we found many significant higher-order interaction terms, making results difficult to interpret. In addition, ordering individual subjects on a scale, as the risk score does, is not as useful for planning and implementing prevention programs as is the identification of specific subgroups. To overcome these problems, we used a signal detection model that provides more interpretable results when there are a large number of interactions.[7] This method, which is a form of recursive partitioning, uses baseline characteristics to define distinct subgroups of respondents, which are mutually exclusive and maximally discriminated from each other, on the basis of probability of positive change in risk function score.

The baseline sociodemographic and psychosocial predictor variables were entered into the signal detection analysis along with minimum and maximum values and interval cutpoints (further information is available from the authors upon request). The signal detection algorithm

then examined each variable and its possible cutpoints and selected a variable and cutpoint on the basis of a combined optimal measure of sensitivity and specificity with regard to the outcome measure (cardiovascular disease risk factor change).

After choosing and splitting on the first optimally efficient variable, the signal detection program separately searched each subgroup or "branch" of the first split for the next most efficient variable and cutpoint (Figure 1). This procedure was repeated separately in each subgroup with all the remaining predictor variables. The procedure ended when (1) there were too few subjects in a subgroup for further analysis, (2) no further significant discriminating variable at ($P < .05$) could be found, or (3) no further predictor variables remained.

Results

The cohort treatment sample was composed of 221 women and 190 men aged 25 through 74 years who participated in at least the baseline and final surveys. Of those who participated in the first survey, 70.0% returned for the second survey, 58.7% for the third survey, and 54.0% for the final survey.

The baseline sample consisted predominantly of White adults (92%) who had completed at least high school (86%) and who were married (71%). Sixty-nine percent (n = 284) of the study population showed a positive change in their composite risk factor scores over the 6-year study period.

Figure 1 shows the development of the optimally efficient algorithm for identifying distinct groups on the basis of positive change in cardiovascular disease risk factor score. The first optimally efficient variable ($P < .001$) that distinguished positive changers from negative changers was age (≤55 years vs >55 years). In the older age group (group 1), 83% of the participants showed positive change. No other variable provided significant discrimination within this group.

Among younger participants (≤55 years of age), educational attainment further discriminated respondents. For those with higher educational attainment (>11 years), the next significant split was found for self-efficacy. This variable subdivided the younger subgroup with higher educational attainment into two smaller groups. In the group with lower self-efficacy scores (group 2), 70% showed positive change; in the group with higher scores (group 3), 55% showed positive change. The last subgroup of younger participants was discriminated on the basis of lower educational attainment (≤11 years). This group (group 4) had the lowest proportion of positive changers (42%). After the identification of these four subgroups, no further significant predictors were found and the signal detection test development stopped.

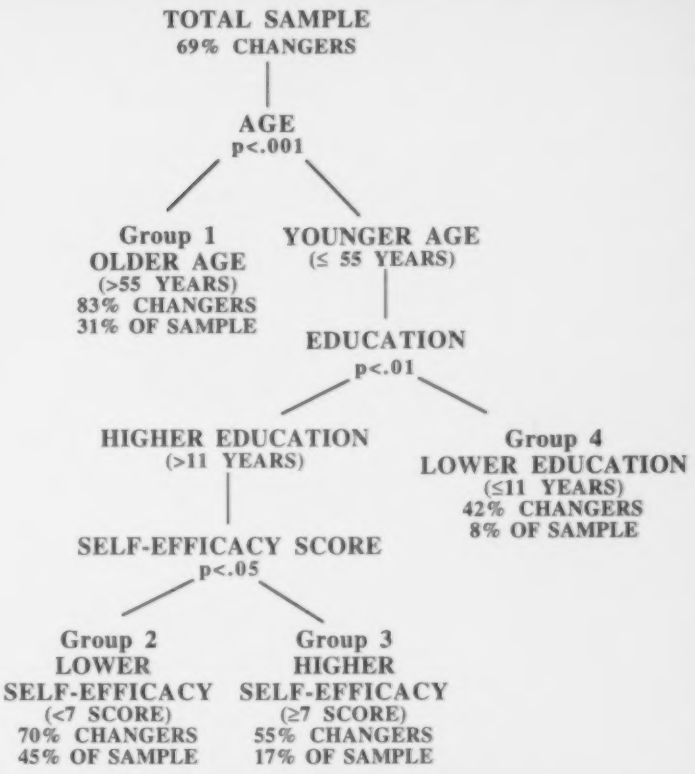

FIGURE 1—Signal detection analysis: development of the optimally efficient algorithm for identifying distinct groups on the basis of positive change in cardiovascular disease risk factor score.

As in all correlational analyses, the factors selected identify respondents at different risk levels but are not necessarily themselves causal factors. Thus, to gain further understanding of the nature of the four subgroups, we examined the profile of each (Table 1). Group 1, the oldest age group and the most likely to show a positive overall risk function change, was distinguished from the other subgroups by higher cholesterol and blood pressure levels and higher prevalence of hypertension at baseline. Group 1 also had the highest perceived risk and highest health media use scores. Group 2, which had lower self-efficacy scores, had a higher proportion of Hispanics, a higher proportion of smokers and heavy smokers, higher rates of hypertension, and higher levels of cholesterol than did group 3. Members of group 3, which had the highest self-efficacy scores, were the youngest participants, the most highly educated, the most likely to be single, and the most likely to be male. They also had the lowest perceived risk and the most positive risk factor profile. Group 4, the group with the lowest proportion of positive changers, had the highest proportion of women, the highest proportion of Hispanics, and the lowest levels of health knowledge.

Discussion

In this paper we provide a prospective examination of factors associated with changes in overall cardiovascular disease risk factor scores in individuals living in

TABLE 1—Baseline Characteristics of Four Change Groups: Men and Women Aged 25 through 74 Years, Stanford Five-City Project, 1979 through 1985

the two Stanford Five-City Project treatment cities that received the 6-year education program. Our objective is to provide researchers who are planning cardiovascular disease community interventions with information about subgroups that are the most likely (or unlikely) to make positive changes in response to intervention programs, especially those involving media interventions. Although other studies have examined the effectiveness of demographic and psychosocial variables in segmenting populations,[29,30] few have examined the relationship between segmentation variables and risk factor changes over time.

Four distinct subgroups of individuals were identified on the basis of changes in their cardiovascular disease risk factor scores. Group 1 (31% of the sample) consisted of older adults who initially had the highest mean blood pressure levels, double the rate of hypertensives of other groups, and the highest mean cholesterol levels. This group had the most positive motivation and information-seeking habits, as indicated by its high perceived risk and health media use scores. Given their psychosocial and physiologic profiles, it is not surprising that members of this group were the most likely to change; therefore, some portion of the change may reflect a regression to the mean phenomenon. Their perception of risk was accurately high, their cardiovascular disease knowledge was adequate, and their health media use was high (providing a relatively information-rich environment via print materials). Moreover, their self-efficacy scores show a confidence about making behavioral changes needed to lower risk. The demographic and psychosocial profile of members of this subgroup, combined with their health media use, make them receptive to public health campaigns that disseminate risk reduction information.

Members of groups 2 and 3, who constituted 62% of the sample, were identified by younger age and higher educational attainment. Group 2 (with 70% changers) was distinguished from group 3 (with 55% changers) by self-efficacy score (5.4 and 7.8, respectively). Group 2 also had a higher smoking rate (32%, vs 26% in group 3), a higher percentage of hypertensives (24%, vs 16% in group 3), and a higher mean cholesterol level (200.3 mg/dL in group 2 and 192.9 mg/dL in group 3). The higher percentage of positive changers in group 2 than in group 3 is most likely explained by group 2's greater cardiovascular disease risk at baseline, which gives a greater possibility for change.

At first glance, the fact that group 3 had a higher level of self-efficacy and a lower proportion of positive changers seems counter to the large empirical literature on self-efficacy and behavior change.[9,14] On closer examination, however, we see that group 3 was the youngest of all groups, the most educated, and the most likely to be single, non-Hispanic, and male. This group was also the healthiest in terms of blood pressure and cholesterol. Thus, while its members' self-efficacy and health attitudes were highest, their low

levels of perceived risk may indicate that they believe they could change but do not see a need to do so. It is also possible that members of this group have already made changes and do not see the need for further change. The effort to reach those who are younger, more educated, and healthier, but less likely to seek health information via the media, may be most successful if prevention is stressed via mainstream formats such as newspaper articles rather than specialized health media such as doctors' columns. Furthermore, strategies that incorporate short-term outcomes and use a social influences framework may be most appealing to this audience.

Like group 1, group 4 is one that could be labeled "high risk," but unlike group 1, group 4 had a low rate of change (42%). Its members were the least educated of all groups (mean of 8.1 years of schooling). Although predominantly White, almost 40% were Hispanic. Over 65% were women. Members of this group had the highest smoking rates, the lowest levels of cardiovascular disease knowledge, the lowest health attitude scores, and the lowest self-efficacy scores. Although it constitutes only 8% of the sample, this group is at high risk for health problems because of its lower socioeconomic status[27,31] and poorer health knowledge and attitudes. Although persons of all educational levels are beginning to show substantial declines in cardiovascular disease risk factors,[32] those with low educational attainment may be unlikely to respond to health education campaigns that are based on a high level of cardiovascular disease knowledge and the initiation of complex actions. It is possible that members of this subgroup were not provided with the requisite skills to perform many of the behaviors promoted by the campaign and that they lived in environments where resources were scarce and where norms did not support positive changes in health. It is clear that more research is needed on how to provide effective health education to those who fit the profile of this subgroup. For example, community interventionists need to gain a better understanding of how poverty and literacy levels, normative beliefs, and communication styles affect behavior change. Furthermore, interventionists need to increase their understanding of the social environments in which adults from lower educational levels reside.[33-37]

Strengths and Limitations

A major strength of the Five-City Project is the opportunity it offers to conduct cohort analyses on large numbers of men and women for whom multiple sociodemographic, psychosocial, and physiologic measurements are available. In addition, participants in the Project are more likely to represent the community than are clinical or volunteer samples, thus enhancing the study's generalizability. Because of the study's location and the type of intervention, the results are most relevant to California communities with campaigns similar to the Five-City Project.

As noted, only 54.0% of those who participated in the baseline survey (1979/80) also participated in the final cohort survey (1984/85). Although the majority of dropouts were out-migrants rather than refusers, dropouts were significantly different from nondropouts on a number of sociodemographic variables. For example, dropouts were significantly younger (mean age 42.2 vs 46.6 years) and less educated (mean years of education 12.5 vs 13.4) than nondropouts.

Another potential limitation of the study is the possible bias that could arise if those with more motivation to change their cardiovascular disease risk factors were more likely to continue participating in the study. We assessed this potential source of error by comparing respondents who participated in at least the baseline and final cohort surveys with those who dropped out after the baseline survey. We found no significant differences between dropouts and nondropouts on a summary index of nine items assessing confidence in changing dietary habits ($P = .15$) or on a single item assessing intention to quit smoking ($P = .71$, smokers only).

Public Health Implications

This study has three important public health intervention implications. First, this research reinforces the work of others in pointing out the need for campaign designers to segment audiences into more homogeneous and identifiable subgroups to enhance the likelihood that each subgroup will be reached effectively. Second, it points out the need to use sociodemographic, psychosocial, and physiologic variables when segmenting audiences. Third, the distinct makeup of the four population subgroups illustrates that communitywide health education campaigns need to develop specific interventions that target different age, socioeconomic, and cultural subgroups to enhance the likelihood that all will be reached. □

Acknowledgments

This research was supported by Public Health Service grant 1RO1-HL-21906 from the National Heart, Lung, and Blood Institute to Dr John W. Farquhar.

The authors gratefully acknowledge the assistance of Drs Stephen P. Fortmann and Erica Frank for valuable comments on the manuscript; Beverly Rockhill, Darius Jatulis, and Jennifer Lin for statistical advice; Patricia Cruz for the preparation of tables; and Donna Balderston, Christine Brereton, Doreen Chapman, Mary Collins, Kathryn Kandler, Jennefer Santee, Sarjeet Singh, and Sammy Van Gundy for their valuable participation in all phases of recruitment and data collection.

Effects of a Restricted Work-Site Smoking Policy on Employees Who Smoke

Janet Brigham, PhD, Janet Gross, PhD, Maxine L. Stitzer, PhD, and Linda J. Felch, MA

ABSTRACT

Objectives. This study evaluated the biological and subjective consequences observed in individual smokers after implementation of a workplace smoking-restriction policy.

Methods. Employees were evaluated for 4 weeks before and 4 weeks after their workplace became smoke-free (n = 34). A comparison group of smokers whose work-site smoking was unrestricted served as controls (n = 33). Daily exposure to tobacco constituents and withdrawal effects were measured.

Results. Smokers at the restricted site had verified smoking reduction (mean = four cigarettes per day) and significantly reduced nicotine and carbon monoxide during the work shift. There were increases in ratings of some common withdrawal symptoms (cravings/urges, concentration difficulties, increased eating, depression). No evidence of compensatory smoking during nonwork hours was found. Overall tobacco exposure, as measured in saliva cotinine, showed a nonsignificant 15% decline.

Conclusions. Workplace smoking restriction markedly altered smoking patterns (i.e., reduced daytime smoking) and reduced cotinine levels to an amount consistent with cigarette reduction. Thus, work-site smoking restriction may promote meaningful, albeit limited, reductions in tobacco exposure and consequent health risks. (*Am J Public Health.* 1994;84:773–778)

Introduction

Many institutions throughout the United States have moved toward restricting smoking in public places, particularly since the Surgeon General's 1986 report on involuntary smoking.[1] Several studies have indicated that the incidence of public smoking changes when restricted-smoking policies are implemented. Stillman et al.[2] reviewed empirical evidence of reduction in smoking at the Johns Hopkins medical institutions and concluded that implementing a smoke-free policy in a large medical center can decrease visible smoking and passive exposure to tobacco smoke. A previous report by Becker et al.[3] indicated that public smoking at the Johns Hopkins Children's Center was virtually eliminated in 1987 by implementation of a smoke-free policy. Recently, Borland et al.[4] reported that Australian smokers exposed to a mandatory work-site smoking ban reduced their smoking by about seven cigarettes per day while working inside and by about five cigarettes per day overall with very little compensatory, or increased, smoking observed outside of work after enforced reduction at work.

Of interest to policymakers and work-site managers are the potential negative side effects of daytime abstinence, which may affect the smoker's behavior (e.g., symptoms of the tobacco withdrawal syndrome), as well as the overall impact on smoking exposure (e.g., compensatory changes in rates of smoking outside the work place). Researchers on smoking cessation have found that some of the symptoms of the tobacco withdrawal syndrome that typically accompany tobacco abstinence[5] are present to a lesser extent in individuals who reduce cigarette consumption or switch to a lower-nicotine-yielding cigarette.[6,7] For example, in the study by Hatsukami et al.,[6] smokers who reduced the number of cigarettes smoked by 50% or reduced the nicotine yield of their cigarettes by about 50% experienced some craving and withdrawal discomfort but reported significantly less discomfort than total abstainers. On the other hand, West et al.[7] found that switching to an ultra-low-yield cigarette did not result in any appreciable reporting of withdrawal distress, except for increased hunger. The mechanisms thought to cause low-level withdrawal symptoms under conditions of restricted smoking are reduction in blood nicotine levels and habit change.

In a related vein, research on restricted smoking in habitual smokers has suggested that smokers may adjust their smoking behavior to offset effects of restricted access or reduced cigarette yield.[8,9] Benowitz et al.[10] found that when smokers reduced their consumption from an average of 37 to 5 cigarettes per day (i.e., a sixfold reduction), the toxicity per cigarette increased threefold because of more puffs per cigarette, longer breath holding, and deeper inhalation, whereas the cumulative daily exposure to tar and carbon monoxide dropped by only about one half. This tendency for smokers to alter their smoking style (e.g., by increasing inhalation or taking more frequent

*$P < .05$.

puffs) could offset the potential health advantages of reducing the number of cigarettes smoked at work. The extent to which smokers engage in compensatory smoking behavior and increase their exposure to toxic constituents of tobacco as a result of restrictions on workplace smoking is unknown.

Among the hospitals joining the smoke-free movement recently was Francis Scott Key Medical Center, part of the Johns Hopkins medical institutions in Baltimore, Md. This institution implemented a hospital-wide smoking ban on July 1, 1989. We used this event as an opportunity to examine the biological, subjective, and behavioral impact of a smoking policy restriction on individual smokers, including objective measures of tobacco smoke exposure. We compared these effects with those in a control group of smokers whose work-site smoking policy remained unrestricted.

Methods

Subjects

Ninety-two smokers were recruited for the present study. All study participants were between 18 and 65 years old and were not seeking treatment to quit smoking. Forty-one smokers were recruited from the Francis Scott Key Medical Center, the site of the smoking ban, through advertisements, flyers, and referrals. Before analysis, four dropped out of the study, and three were omitted from the analysis because of incomplete compliance with the study procedures. The comparison control group was composed of 51 individuals recruited through newspaper advertisements at several nearby hospitals that had no restricted smoking policy. Of those initially enrolled, 10 failed to complete the study, 1 quit smoking during the study, and 7 were excluded from analyses because their mean number of cigarettes per day before the smoking ban exceeded the maximum number observed in the restricted-smoking group. Consequently, 67 participants were included in the final analysis of the data.

Table 1 shows the demographic, smoking, and psychological characteristics of the two groups at baseline. The groups were similar with respect to mean age, distribution of gender, and occupational status. The self-reported amount of smoking was significantly higher in the control group (t (60) = 2.02, $P < .05$). However, the groups did not differ on the biological indices of tobacco exposure, which included expired-breath carbon monoxide and saliva cotinine and nicotine. The groups also differed with respect to the total withdrawal score and the score on the Depression-Dejection subscale of the Profile of Mood States. In both cases, the control subjects had higher scores, indicative of greater distress.

Procedures

All subjects participated in data collection sessions at the research laboratory after their work shifts. Experimental (restricted smoking) subjects attended a laboratory data collection session once per week for 4 weeks before and 4 weeks after implementation of the smoking ban. Control subjects attended sessions at their work site once weekly for 8 consecutive weeks. Informed consent, which had been approved by the Francis Scott Key Medical Center Institutional Review Board, was obtained from all subjects after the study was explained at the first session. Subjects were paid $100 for successfully completing the study.

Measures

At each study contact, behavioral, biological, and subjective report data were collected.

Smoking amount. Smoking amount was assessed via self-report and by collection of cigarette butts for designated time periods. To determine the pattern of smoking during the work shift, subjects were asked at each lab visit to recollect and report the number of cigarettes smoked at their workstation, at other sites inside the building, and at any sites outside the building for the time period of the most recent work shift. To estimate 24-hour smoking amount and toxic exposure to tobacco constituents, subjects collected their cigarette butts for the 24-hour period before the lab session. Three separate plastic collection bags reflected three intervals of the day: (1) between the end of work and bedtime the previous day, (2) between arising and going to work the day of the lab session, and (3) during work the day of the lab session. The number of cigarette butts per interval and the weight of the butts from each interval were assessed. Thus, for the period of the work shift, both self-report and butt count data were available. Butt

weight was used as an indirect measure of smoking intensity.[9] Like butt length, butt weight indicates the amount of material in the cigarette left unsmoked. Butt length provides an indirect measure of smoking intensity and relative toxicity because tar and carbon monoxide delivery increase logarithmically as cigarettes are smoked to shorter butt lengths.[11] Before weighing, all butts were desiccated until the moisture content in the desiccator was below 20%.

Biological exposure. At each lab session, subjects provided saliva samples, which were then analyzed for nicotine and cotinine (a metabolite of nicotine with a half-life of 18–20 hours) by using gas chromatography (analyses conducted by Labstat, Inc, Kitchener, Ontario, Canada). Breath carbon monoxide samples, which reflected recent exposure to tobacco smoking, were measured by using a Vitalograph breath analyzer (Lenexa, Kans).

Subjective report. Three subjective measures were used to assess withdrawal symptoms associated with smoking reduction and the impact of those symptoms on participants' work. A withdrawal symptom questionnaire adapted from that used by Hughes and Hatsukami[5] assessed subjects' ratings of 18 symptoms (0 = none to 3 = severe), many of which characterize the DSM-III Tobacco Withdrawal Syndrome. This measure has been widely used in smoking research and has good psychometric properties.[12] The Profile of Mood States,[13] a widely used 65-item self-report questionnaire, was used to measure overall mood disturbance. This questionnaire yields factor scores on subscales of Tension-Anxiety, Depression-Dejection, Anger-Hostility, Vigor, Fatigue, Confusion-Bewilderment, Friendliness, and Total Mood Disturbance. A work attitude and performance questionnaire developed by the investigators solely for purposes of this study was designed to elicit subjects' ratings (on a scale of 0 to 10) regarding their concentration ability and productivity at work, relations with coworkers, work enjoyment and satisfaction, and overall sense of well-being.

Statistical Analysis

We analyzed the data with a two-factor, mixed-model analysis of variance using SPSS-X for the Macintosh. The grouping factor was restricted smoking (smoking ban) vs control (unrestricted smoking); the repeated-measures, within-subject factor was time: preban (weeks 1–4) vs postban (weeks 5–8). All tests of significance were two tailed. Posthoc comparisons of preban and postban interactions were conducted by using Tukey's Honestly Significant Difference (HSD) test.

Results

Work-Site Smoking

Amount and intensity. Based on the self-reported smoking amount, consumption of cigarettes during work hours by subjects in the restricted group dropped significantly as a function of the ban ($F[1, 65] = 15.7$, $P < .0001$). Restricted subjects reported an average of 7.57 (SD = 4.7) cigarettes per day during study weeks 1–4 (before the ban) vs 3.64 (SD = 4.9) cigarettes per day during study weeks 5–8 (after the ban) (Tukey's HSD $q = 9.15$, $P < .001$). None of the subjects in the restricted group quit smoking during the study. The smoking pattern for control subjects did not differ over time. The mean rate of smoking was 10.02 (SD = 2.9) cigarettes per day before the ban vs 9.53 (SD = 4.8) cigarettes per day after the ban. Reported smoking rates were highly similar to those determined with the butt count procedure for this time interval. Although there was a small discrepancy between self-report and butt count with respect to absolute numbers of cigarettes, there was in both cases a four-cigarette-per-day reduction in smoking during work hours in the restricted group as a function of the ban, vs less than a one-cigarette-per-day change in the control group.

The average butt weight per cigarette smoked during work was calculated from the returned butts for this period. There were no effects on butt weight found from the repeated-measures analysis of variance (ANOVA). In the restricted group, the mean butt weight was 0.36 g (SD = 0.11 g) before the ban and 0.35 g (SD = 0.09 g) after the ban. For the control group, the means were 0.38 g (SD = 0.06 g) and 0.36 g (SD = 0.08 g), respectively.

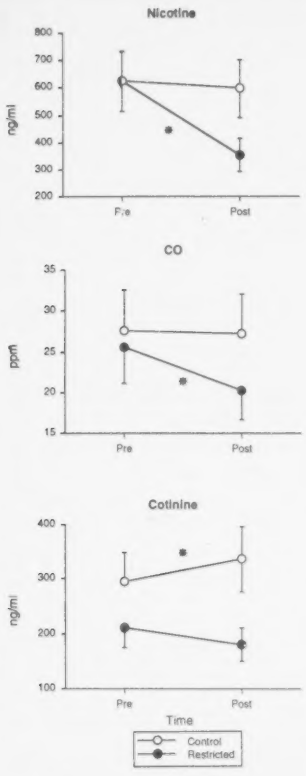
Smoking location. An analysis of self-reported amount of smoking at the various work-shift locations showed significant interactions for smoking at the workstation ($F[1, 65] = 41.6$, $P < .0001$) and for smoking outside the building ($F[1, 65] = 19.6$, $P < .0001$). Restricted subjects reported an average of 5.89 (SD = 4.8) cigarettes per day at the workstation before the ban compared with 0.69 (SD = 2.2) cigarettes after the ban ($q = 12.25$, $P < .01$). The reverse pattern was observed for their smoking behavior outside the building. Before the ban, the restricted group smoked an average of 0.83 (SD = 1.0) cigarettes per day outside the building compared with 2.51 (SD = 1.7) cigarettes after the ban ($q = 6.7$, $P < .01$). The ban on smoking had no effect on behavior at other locations within the building. Restricted subjects reported a mean of 0.84 (SD = 1.1) cigarettes per day before the ban and a mean of 0.45 (SD = 1.2) cigarettes per day after the ban at other building sites. Control subjects did not change their smoking patterns over time (mean number of cigarettes at workstation = 6.8; mean at other inside locations = 1.2; mean outside building = 1.8).

Before implementation of the smoking ban, 82% of the subjects in the restricted group reported ever smoking at their workstations. After implementation of the ban, this figure decreased to 18%. The percentage of control subjects smoking at the workstation during these two time periods was 88% and 85%, respectively. The percentage of subjects who reported going outside the building to smoke during the workday increased in the restricted group from 68% to 97% as a function of the ban. The percentage of control subjects reporting smoking outside the building during these two time periods changed only slightly from 55% to 49%.

Biological exposure. The repeated-measures ANOVA revealed significant interactions on both saliva nicotine and breath carbon monoxide measures, which reflected changes in work-shift smoking behavior. As shown in Figure 1, average saliva nicotine measured at the end of the work shift in the restricted group decreased from 623 ng/mL before the ban to 354 ng/mL after the ban ($q = 5.11$, $P < .01$), whereas there was no change in the control group. There was also a significant decrease in breath carbon monoxide in the restricted group from 25.6 to 20.2 ppm ($q = 5.43$, $P < .01$) vs no change in the control group.

Smoking during Off-Work Hours

Amount and intensity. Butt count data revealed that the number of cigarettes smoked per day during off-work hours did not change significantly in either group as a function of the ban (mean number of cigarettes [restricted group] = 12.56 preban [SD = 5.7] vs 11.44 postban [SD = 6.4]; mean number of cigarettes [control group] = 11.99 preban [SD = 4.4] vs 11.14 postban [SD = 4.8]). Nor did the mean butt weight of cigarettes collected



Note. Bars reflect the standard deviation. The preban point represents the average of four weekly data collections during weeks 1–4; the postban point represents the average of four weekly data collections during weeks 5–8. Participants in the restricted group were banned from smoking at the work site during the postban period. Asterisks indicate differences between the means according to Tukey's HSD. Both nicotine and CO levels changed significantly across the time periods in the restricted group ($P < .01$).

FIGURE 1—Saliva nicotine, expired breath carbon monoxide (CO), and saliva cotinine levels are shown for the preban and postban time periods.

from the before-work and after-work assessment periods differ as a function of the smoking ban implementation. For the restricted group, the mean butt weight per cigarette for cigarettes smoked outside work before the ban was 0.33 g (SD = 0.11 g) vs 0.34 g (SD = 0.13 g) for the period after the ban. For the control group, the mean outside-of-work butt weights before and after the ban were 0.36 g (SD = 0.12 g) and 0.33 g (SD = 0.14 g), respectively. The mean weight of butts collected after work was highly similar to the mean weight of butts collected before work.

Biological exposure. Cotinine levels were significantly higher in the control group overall ($F[1, 65] = 13.7, P < .0001$), and there was a significant interaction between group and time ($F[1, 65] = 17.0, P < .0001$). As shown in Figure 1, cotinine, which reflects overall nicotine exposure for the previous several days, decreased by 15% in the restricted group from 211 to 180 ng/mL ($q = 3.61, P > .05$) and increased by 13.5% in the control group from 296 to 336 ng/mL ($q = 4.62, P < .01$). Subjects were categorized according to whether their average cotinine levels increased or decreased from the preban to the postban period. In the restricted group, 71% of the subjects showed a reduction in cotinine levels, with a mean decrease of 55.9 ng/mL (range = 0.7–120.6 ng/mL). In the control group, 33% of the subjects showed a reduction in cotinine levels, with a mean decrease of 39.8 ng/mL (range = 8.1–137.7 ng/mL). In the restricted group, 29% of the subjects showed an increase in cotinine levels, with a mean increase of 28.4 ng/mL (range = 7.4–83.6 ng/mL). In the control group, 67% of the subjects showed an increase in cotinine levels, with a mean increase of 80.5 ng/mL (range = 1.3–227 ng/mL). A chi-square test on the number of subjects with increasing vs decreasing cotinine levels was significant (χ^2 [1] = 9.32, $P < .002$).

Subjective Reports

Withdrawal symptom questionnaire. Table 2 shows the mean values and standard deviations for the withdrawal items with significant interaction terms, significant changes from the preban to the postban period in the restricted group, and significant group differences during the postban period. Restricted subjects reported significant increases in 4 of 18 withdrawal symptom items (craving for cigarettes, difficulty concentrating, depression, and increased eating) after implementation of the smoking ban. However, the magnitude of these changes across the two time periods was less than or equal to 0.5 points, and the total withdrawal score did not increase significantly. Control subjects, on the other hand, reported significant decreases over time on five withdrawal items (urges to smoke, irritability, restlessness, impatience, headaches) and a significant (3.23-point) decrease in total withdrawal score (all P values $< .05$). Only scores on the craving-for-cigarettes and urges-to-smoke items were significantly higher in the restricted group vs the control group during weeks 5–8 after the ban ($P < .01$).

Profile of Mood States. The Total Mood Disturbance score, shown in Table 2, had a significant interaction ($F[1, 65] = 5.39, P < .02$) with an increase in the restricted group scores and a decrease in the control group scores. However, these within-group changes were not statistically significant in posthoc testing. Two interactions on the Profile of Mood States factors of Tension-Anxiety ($P < .03$) and Depression-Dejection ($P < .002$) reflected significant preban group differences. In both cases, the control group had higher scores, indicating greater symptom reporting. The restricted group showed no significant changes in factor scores between the preban and the postban periods, although scores on the Fatigue factor decreased significantly over time in the control group ($P < .05$).

Work attitudes and performance. Four of the five measures of work satisfaction and the overall well-being score had significant interactions in the repeated-measures ANOVAs ($P < .03$). Posthoc analyses shown in Table 2 revealed that restricted group members noted small but significant decreases on self-reports of concentration, ($P < .05$), productivity ($P < .01$), relations with coworkers ($P < .05$), and overall well-being ($P < .05$). Control subjects showed no changes over time on the work-productivity indices. Only the overall well-being item had a significant between-group difference after the ban, with the restricted group reporting a lower score ($q = 4.39, P < .05$).

Discussion

This study showed reduced daytime smoking after implementation of a workplace smoking ban. Specifically, smoking during work hours was reduced by an average of four cigarettes per day. This reduction is consistent with the self-report data from Johns Hopkins Hospital smokers[2] and with the results reported for light and moderate smokers in the Australian Public Service.[4] The present findings are also consistent with a recent report of a cross-sectional study by Kinne et al.,[14] which found that men employed in work sites with restrictive smoking policies

smoked fewer cigarettes overall than did men employed in settings without restrictive smoking policies. We found that the decrease in smoking measured at the end of the work shift was corroborated by reductions in the biological measures of salivary nicotine and expired breath carbon monoxide, both of which reflect recent smoking exposure. Further, questions regarding locations where employees smoked revealed the expected shift from smoking at the workstation to smoking outside the building as a result of the smoking ban.

Although it is clear that exposure during the work shift declined, it is important to consider the impact of the ban on overall smoking behavior and tobacco smoke exposure. The most striking finding was that smokers did not compensate for the pack per week reduction either by increased smoking outside of work or by more intensive smoking. Thus, a reduction in overall exposure might be expected. Cotinine levels, which reflect accumulated nicotine exposure over several previous days, declined in the restricted group from 211 to 180 ng/mL, a 15% statistically nonsignificant reduction. Because this reduction suggested an overall trend in reduced exposure, we further examined the data for changes in individual subjects' cotinine levels. Although a full 71% (n = 24) showed some cotinine reduction, only 38% (n = 13) showed a reduction of 50 ng/mL or more. The average postban cotinine level observed among those who had reduced cotinine levels was 167.6 ng/mL (SD = 97.0 ng/mL). This level was only slightly lower than 180 ng/mL, the average postban level for the entire restricted group, and indicated continued moderate levels of smoking exposure despite the trend toward reduction in many subjects.

The increased mean cotinine level observed for control subjects was unexpected (particularly in its magnitude) and was influenced by several individuals with especially large increases (21% of subjects had cotinine increases of > 100 ng/mL). It is unlikely that this observed increase reflects a population tendency toward increasing cotinine levels over time. It is possible that some control subjects reduced their smoking initially as a result of entering a study about smoking behavior.

A larger sample size would have been helpful in assessing the statistical significance of reductions in cotinine levels resulting from a work-site smoking ban. In terms of understanding the clinical significance, however, changes in cotinine levels must be interpreted in light of observed changes in overall tobacco consumption. The work-shift smoking reduction observed was equivalent to one pack of cigarettes per week (4 cigarettes/day × 5 days/week). In a one-pack-per-day smoker, this would amount to a 14% reduction in smoking exposure over a 1-week period. In fact, this smoking reduction is consistent with the observed 15% reduction in cotinine levels and also consistent with the conclusion that there were no compensatory changes in smoking topography or increases in numbers of cigarettes smoked outside of work. Although this is a small reduction in exposure for individual subjects, at the population level, a 15% reduction in tobacco exposure overall could confer an appreciable reduced health risk given that there is strong evidence for a dose-response relationship between smoking and health effects.[15]

Smokers undergoing an abrupt work-site smoking ban showed statistically significant increases in four of the most reliably reported tobacco withdrawal symptoms: difficulty concentrating, craving cigarettes, increased eating, and depression. The subjective report scores of control subjects tended to decrease over time, either because of increases in smoking exposure (as suggested by the cotinine data) or because of a nonspecific tendency for regression to the mean. Restricted smokers reported some difficulties with work productivity and a decline in general well-being. Further, scores on the craving-cigarettes and urges-to-smoke items were significantly higher for the restricted group than for the control group during weeks 5–8 after the ban. Although the magnitude of average change on these measures was quite small, subjects exhibited notable individual differences. The number of restricted smokers who had a mean total withdrawal symptom score of at least "moderate" (> 18) increased by 56% from the preban to the postban period (four subjects at preban and nine at postban). In contrast, for the control group, the number of subjects with moderate withdrawal scores remained steady over time: six and five, respectively. It would be interesting to follow the pattern of the withdrawal symptoms for a longer duration to determine whether there are any lasting effects of work-site smoking restrictions. The importance and increasing popularity of work-site smoking restrictions underscore the need to educate employees and employers alike about the side effects of abstinence during the work shift.

In summary, implementation of a total ban on indoor work-site smoking resulted in a decrease in smoking during the work shift, as verified by reduced

TABLE 2—Preban and Postban Mean Values for Questionnaire Items

Questionnaire Item	Restricted Group (n = 34)		Control Group (n = 33)

nicotine and carbon monoxide levels measured at the end of the work shift. The reported reduction in numbers of cigarettes smoked was equivalent to about one pack per week. The cotinine analysis suggested, however, that the smoking ban intervention may provide limited immediate health benefits to smokers themselves in terms of tobacco exposure reduction, while producing minor withdrawal discomfort. Another potential health benefit for smokers that has received some support in the literature is that work-site smoking bans have the additional effect of motivating a small number of smokers to quit completely.[16] However, this effect was not observed during the relatively brief assessment period of this investigation. □

Work-Site Cholesterol Screening and Dietary Intervention: The Staff Healthy Heart Project

Alexandra Barratt, MBBS, MPH, Robert Reznik, MD, MBBS, MSc, Les Irwig, PhD, MBBCh, America Cuff, BSc, Judy M. Simpson, PhD, BSc, Brian Oldenburg, PhD, BSc, John Horvath, MBBS, FRACP, and David Sullivan, MBBS, FRACP, FRCPA, for the Steering Committee of the Staff Healthy Heart Project

ABSTRACT

Objectives. The Staff Healthy Heart Project was established to run a work-site cholesterol screening project and a randomized controlled trial of dietary interventions.

Methods. Screening was offered to all staff at six Australian hospitals. Participants with blood cholesterol of 5.2 mmol/L (200 mg/dL) or above were randomly allocated to receive screening only (control group), a self-help package, or a nutrition course. Participants were seen 3 and 6 months after intervention to measure blood cholesterol and dietary changes.

Results. Eighty percent of available staff (n = 2638) were screened. Of those eligible, 67% (n = 683) entered the trial. Follow-up measures of blood cholesterol and dietary intake were obtained for 63% and 38% of trial participants, respectively. A reduction in reported dietary fat was found for all groups, but there were no significant differences between groups. Reported dietary fiber rose by 0.6 g/MJ/day for those in the nutrition course. There were no changes in total blood or high-density lipoprotein cholesterol.

Conclusions. Cholesterol reduction was not demonstrated, but this result is difficult to interpret given the poor ongoing participation rates. Strategies to improve ongoing participation in work-site projects are needed to achieve adequate assessment of dietary interventions used in cholesterol screening. (*Am J Public Health.* 1994;84:779–782)

Introduction

Cholesterol levels are higher than desirable (above 5.2 mmol/L or 200 mg/dL) in approximately half of all adults in Australia and the United States.[1,2] Regular cholesterol checks for all adults have been recommended,[3,4] and work-site cholesterol screening has become a popular strategy for achieving this objective.[5] However, work-site studies often have major methodological problems, including lack of evaluation, and low participation rates.[5,6] Very few work-site cholesterol screening programs have been evaluated by randomized controlled trials, and these have yielded conflicting results, ranging from a net cholesterol reduction of 6.4% in the treatment group in a study of 145 participants[7] to no significant effect in a study of 2489 subjects.[8] Participation rates vary widely (e.g., from 35%[8] to 86%[9]), as do dropout rates (e.g., from 12%[10] to 43%[7]). These problems have made it difficult to draw conclusions about the efficacy of work-site cholesterol screening.

The Staff Healthy Heart Project was established to examine the feasibility of conducting a large work-site cholesterol screening project and to evaluate by randomized controlled trial two dietary interventions to lower cholesterol.

Methods

The project was conducted between 1988 and 1991 at the Royal Prince Alfred Hospital, a tertiary referral center and teaching hospital in Sydney, and at five nearby smaller hospitals. At the outset, a steering committee of 16 members was established to be responsible for the design and implementation of the study. The committee had representatives of senior management staff, the major on-site unions, and the Sports and Social Club at the Royal Prince Alfred Hospital, as well as members representing medical, health promotion, and research interests.

Screening

Two health educators took a mobile screening unit to all major work areas during day and night shifts. Screening was free. Participation was estimated from staff lists supplied by the personnel departments and represents the proportion of staff screened after vacant, "frozen," casual, and off-site positions were deducted from total staff numbers.

Cholesterol was measured by rapid dry chemistry analysis, using the Boehringer-Mannheim Reflotron system. This sample was used for screening purposes only and was available in 3 minutes. Participants' weight and height (without shoes), systolic and diastolic blood pressure (according to standard guidelines[11]), and exercise and smoking habits (elicited by standard questions[1]) were also mea-

sured. Limited sociodemographic data were collected. Results were reviewed with each participant, and brief advice was given based on pamphlets supplied by the National Heart Foundation. Participants with blood pressure above 140/90 were referred for medical care.

Trial of Dietary Interventions

Eligible employees were those who had cholesterol levels at screening of 5.2 mmol/L or above, were permanent staff, and were fluent in English. Participants were allocated at random in a ratio of 3:3:1 to the control group (screening only) and two intervention groups (self-help package and nutrition course, respectively). For ethical reasons, participants whose screening cholesterol was 7 mmol/L or above were allocated only to intervention groups.

At baseline, venous blood was analyzed for total and high-density lipoprotein cholesterol level at the Biochemistry Department at the Royal Prince Alfred Hospital. All participants were asked to complete a 179-item quantitative food frequency questionnaire (FREQPAN[12]).

Participants were asked (in up to two letters and two phone calls) to attend follow-ups 3 and 6 months after intervention. Blood cholesterol was measured as at baseline, and participants were weighed. A repeat food frequency questionnaire was administered at the 6-month follow-up only. Results of all cholesterol tests were mailed to all participants.

The dietary interventions were consistent with dietary recommendations to reduce total and saturated fat and increase fiber intake.[13] The self-help package, "Food for a Healthy Heart," was a low-intensity intervention. The package included a workbook with educational material and aids to behavior change such as quizzes, shopping guidelines and recipes, a 3-minute video outlining the principles of a healthy heart diet, and a monitoring sheet of suggested dietary behavior changes. The nutrition course, "More Fiber, Less Fat," consisted of five 1-hour sessions led by a dietitian, with 12 to 15 participants per class. The educational content was similar to that of the self-help package, but the sessions provided an opportunity to demonstrate and discuss a standardized series of topics, including the fat and fiber content of foods, food labeling, why people eat too much fat and not enough fiber, and barriers to dietary change. Participants in the sessions were able to taste low-fat, high-fiber recipes. A workbook included information and activities for each session. Participants were consulted about their preferred times to attend and were advised of class times by mail and telephone. Half an hour of paid time off work to attend each class was negotiated.

Participants with a body mass index ([weight in kilograms]/[height in meters]^2) of more than 25 were classified as overweight, and those with a body mass index of more than 30 as obese. The food frequency data were coded and adjusted for serving size according to FREQPAN guidelines.[12] Nutrients were expressed as a proportion of total energy to adjust for differences in energy intake. Changes in nutrient intake, weight, and cholesterol were calculated for each individual at each follow-up attended, and the mean change and 95% confidence interval were calculated for each intervention group. Each intervention group was compared with the control group for significant differences, except for changes in blood cholesterol. For blood cholesterol, comparisons were made to take into account the allocation of people with cholesterol levels of 7 mmol/L or above to intervention groups only (the control group was compared with a subset of the self-help group who had screening cholesterol levels of less than 7 mmol/L [self-help package—low], and the whole of the self-help group was compared with the whole of the nutrition course group). The original allocation to experimental groups was preserved for all analyses. Differences between groups were tested with chi-square and t tests for independent samples for categorical and continuous data, respectively. Two-sided tests of significance at the .05 level were used throughout. The Keys[14,15] and Hegsted[16,17] equations were used to predict the mean change in blood cholesterol from the observed dietary changes for each intervention group.

Results

Results of Screening

A total of 2638 people, approximately 80% of available staff, were screened. The median age was 35 years (range = 15–79, mean = 36.8, SD = 11.5), and 73% of the participants were female. Most (70%) spoke only English; more than 40 other languages were spoken, most commonly Greek, Yugoslav, Chinese languages, Italian, and Spanish.

With respect to cholesterol, 47% of the men and 42% of the women had levels of 5.2 mmol/L or above, and 7% of the men and 5% of the women had levels of 7 mmol/L or above. Almost half (47%) of the men, and 36% of the women, were overweight; 10% of the men and 12% of the women were obese. Over half the sample (53% of the men and 57% of the women) reported engaging in no regular vigorous exercise (e.g., football, keep-fit classes) in the preceding 2 weeks. A quarter of the women and 30% of the men reported current smoking. Only a small proportion (7% of the men and 3% of the women) were found to have high blood pressure (diastolic pressure above 90 mm Hg).

Results from the Trial of Dietary Interventions

Of those eligible for the trial, 67% (n = 683) agreed to participate. Refusers were significantly more likely to be male and to be smokers and were on average 2 years younger. The participants were allocated into groups as follows: screening only (control), 259; self-help, 310; and nutrition course, 114. A baseline food frequency questionnaire was obtained from 79% of the participants. Of participants allocated to the nutrition course, 38 (33%) failed to attend any classes, 40 (35%) attended three or more classes, and 36 (31%) attended one or two classes.

Follow-up cholesterol samples were obtained from 61% and 63% of the participants at the 3- and 6-month follow-ups, respectively. Repeat measures of weight were obtained from 51% (at 3 months) and 49% (at 6 months) of the participants. Compared with those seen at follow-up, dropouts were significantly heavier and had higher blood pressure at screening, but the two groups were similar with respect to gender, age, mean baseline cholesterol level, exercise, and smoking. A repeat food frequency questionnaire was completed by 48% of the trial participants; paired baseline and follow-up food frequency questionnaires were available for 261 (38%) of the participants. Participants who failed to complete both food frequency questionnaires were younger (3 years on average) and were more likely to be male and to smoke.

Of the 261 paired questionnaires, 10 were excluded from analysis because of extreme values of reported energy intake (outside the 1st and 99th percentiles) or extremely large drops (greater than 10 MJ) in energy intake.

Compared with the other groups, the nutrition course significantly reduced reported total energy intake and increased fiber intake (Table 1). A reduction in total and saturated fat was reported in all

TABLE 1—Baseline Intakes of Energy, Total Fat, Saturated Fat, and Fiber and Change at 6-Month Follow-Up, by Intervention Group

Group	Energy, MJ		Total Fat, % of Total Energy		Saturated Fat, % of Total Energy		Fiber, g/MJ	
	Baseline	Change at 6 Months	Baseline	Change at 6 Months	Baseline	Change at 6 Months	Baseline	Change at 6 Months
Screening only	9.2	−1.1[a]	36.8	−2.0[a]	13.8	−1.0[a]	2.9	+0.1
Self-help package	8.7	−0.9[a]	37.3	−2.4[a]	14.2	−1.7[a]	2.7	+0.2[a]
Nutrition course	10.0	−2.1[a,b]	37.5	−2.5	13.9	−1.7	2.7	+0.6[a,c]

Note. Paired baseline and follow-up questionnaires were obtained for 261 participants (38% of the total n of 683). Ten questionnaires were excluded from analysis because of extreme values; therefore, the table presents data for 251 participants.
[a]95% confidence interval does not include zero.
[b]Change in nutrition course group is significantly different from change in self-help package group ($P = .04$) and change in screening-only group ($P = .05$).
[c]Change in nutrition course group is significantly different from change in screening-only group ($P = .04$).

groups, but the reduction was not significantly greater in either intervention group than in the control group. There were no changes in intake of polyunsaturated or monounsaturated fats.

There were no changes in mean cholesterol level in any group at the 3- or 6-month follow-up (Table 2). The maximum possible decrease in cholesterol (from the lower bound of the 95% confidence interval) was no more than approximately 4% for any group. There were no changes in high-density lipoprotein cholesterol. The maximum decrease in cholesterol predicted from the observed dietary changes was 0.12 mmol/L (2%) for those in the nutrition course.

A mean weight loss of 0.9 kg for the nutrition course group was observed at the 3-month follow-up, but this change was not significantly different from weight changes in the other groups. At 6 months participants in the nutrition course continued to show a 0.25-kg mean weight loss, a statistically significant loss compared with that of the screening-only group ($P = .04$).

TABLE 2—Baseline Cholesterol Levels (mmol/L) and Changes at 3 and 6 Months, by Intervention Group

Group	Baseline Level (n = 668)	Change at 3 Months (n = 417)		Change at 6 Months (n = 430)	
		Mean	95% CI	Mean	95% CI
Screening only	5.82	−0.07	−0.19, +0.05	−0.10	−0.22, +0.01
Self-help package—low	5.79	−0.05	−0.16, +0.05	−0.01	−0.10, +0.09
Self-help package	5.99	−0.05	−0.15, +0.04	−0.02	−0.10, +0.07
Nutrition course	6.16	+0.06	−0.14, +0.26	−0.05	−0.25, +0.15

Note. CI = confidence interval. The control group was compared with the subset of participants in the self-help package group whose screening cholesterol was below 7.0 mmol/L (self-help package—low); the whole of the self-help package group was compared with the whole of the nutrition course group (see Methods).

Discussion

An effective union between academic medicine and the work site is needed to exploit the full potential of work-site health promotion.[18] In the Staff Healthy Heart Project a major effort was made to achieve an effective collaboration among members of the steering committee. Broad agreement on the risk factors to be addressed and the interventions to be used was achieved among researchers, management, and unions. Management and union representatives were then able to negotiate agreements on provision of time off work and use and confidentiality of data. The head of each department was asked personally to support the project, to allocate a room for screening, and to allow staff time away from their duties to participate. This cooperation among researchers, management, and staff was probably responsible for the high participation in screening. The participation rate of about 80% compares favorably with those of other work-site trials, including the World Health Organization European trial in which participation rates ranged from 75% to 89%.[9]

The recruitment rate (67% of eligible staff) compares well with rates of 50% or less in other work-site trials of cholesterol intervention.[7,8] Women, older participants, and nonsmokers were more likely to be recruited. However, the relatively high recruitment rate in this population may have resulted in the inclusion of participants who were not sufficiently motivated to complete the trial. In contrast, Edye et al. recruited only 35% to 45% of participants initially, but retained almost 80% after 3 years.[8] These authors also noted that young women were more likely to drop out. Our study population was unusual in that it was predominantly young and female, and this characteristic may have increased the difficulty of achieving ongoing participation.

Organizational factors are also considered important determinants of participation.[19] Although screening was very convenient, follow-up was less convenient. Participants had to leave their work areas and walk to the staff clinic; follow-up took about 15 minutes at 3 months and about 45 minutes at 6 months (to complete the food frequency questionnaire in addition to the other measures). Participants also had to leave their work areas to attend the nutrition sessions, and many reported difficulty in leaving because of the pressure of work, even though time off work to attend had been arranged. However, in another work-site trial of nutritional classes, the proportion attending no classes (32%) was similar to that in our trial.[7] Follow-up rates were also reduced by the high staff turnover at

this work site; approximately one quarter of those who did not participate in follow-up had resigned or retired.

Finally, follow-up rates varied by outcome measure and were worst for the food frequency questionnaire. The baseline response rate was 79% (similar to that reported by other authors using food frequency questionnaires[20,21]), so the follow-up rate was limited to a proportion of these participants. The questionnaire was quite long and detailed and some participants were reluctant to spend the time needed to complete it, particularly for a second time. However, as no brief, valid, self-report measure of fat intake was available, we chose the food frequency questionnaire as the most appropriate and practical form of dietary assessment for this study.

Each intervention group reported appropriate dietary changes, including reductions in total and saturated fat intake. In addition, participants in the nutrition course increased their fiber intake and reduced their weight, compared with the control group. No benefit for intervention groups in terms of cholesterol reduction was demonstrated, although this result should be interpreted with caution in view of the low ongoing participation rates.

Conclusions

This project demonstrated that a large work-site screening program is feasible and high rates of initial participation can be achieved. The dietary interventions achieved some self-reported dietary change, but no reduction in blood cholesterol was demonstrated. However, this result is difficult to interpret because of the low rates of ongoing participation in the trial. Strategies to maintain high rates of participation beyond the initial stages of work-site projects are required. These strategies might include ways of making programs more accessible and convenient for staff. Such strategies would make a major contribution to the evaluation of dietary interventions used in cholesterol screening programs. □

Acknowledgments

Funding for this project was received from the Central Sydney Area Health Service, Royal Prince Alfred Hospital, the National Heart Foundation of Australia, and the National Health and Medical Research Council (through the Public Health Research and Development Committee). Additional sponsorship was received from the Australian Nutrition Foundation; Pfizer Pty Ltd; Becel Heart Care Information Service; Merck, Sharp & Dohme; SP Agencies; and Reebok Australia.

We would like to acknowledge the contribution made to this project by Dr Sue Morey, Chief Medical Officer, New South Wales Department of Health (formerly Director, Department of Community Medicine, Royal Prince Alfred Hospital) in establishing the project, and by the other members of the Steering Committee—Prof Douglas Baird, Chairman, Central Sydney Area Health Service; Ms Jo Rogers, Australian Nutrition Foundation; Dr Phil Harris; Dr Ian Caterson; Ms Kate Hogan; Ms Marilyn Wise; Ms Vanessa Child; Ms Katherine Maxwell; Mr Terry Conlon; and Ms Annabelle Harman of Royal Prince Alfred Hospital—who have provided much support and assistance.

Improving Dietary Behavior: The Effectiveness of Tailored Messages in Primary Care Settings

Marci Kramish Campbell, PhD, RD, MPH, Brenda M. DeVellis, PhD, Victor J. Strecher, PhD, MPH, Alice S. Ammerman, DrPH, RD, Robert F. DeVellis, PhD, and Robert S. Sandler, MD, MPH

ABSTRACT

Objectives. To achieve the *Healthy People 2000* objectives, public health professionals must develop effective dietary interventions that address psychosocial and behavioral components of change. This study tested the effect of individually computer-tailored messages designed to decrease fat intake and increase fruit and vegetable intake.

Methods. Adult patients from four North Carolina family practices were surveyed at baseline and then randomly assigned to one of two interventions or to a control group. The first intervention consisted of individually computer-tailored nutrition messages; the second consisted of nontailored nutrition information based on the 1990 *Dietary Guidelines for Americans*. Patients were resurveyed 4 months postintervention.

Results. The tailored intervention produced significant decreases in total fat and saturated fat scores compared with those of the control group ($P < .05$). Total fat was decreased in the tailored group by 23%, in the nontailored group by 9%, and in the control group by 3%. Fruit and vegetable consumption did not increase in any study group. Seventy-three percent of the tailored intervention group recalled receiving a message, compared with 33% of the nontailored intervention group.

Conclusions. Tailored nutrition messages are effective in promoting dietary fat reduction for disease prevention. (*Am J Public Health.* 1994;84:783–787)

Introduction

The *Healthy People 2000 Objectives for the Nation* recommend that Americans decrease dietary fat to 30% or less of their total caloric intake and increase fruit and vegetable consumption to five or more daily servings in order to promote health and prevent diet-related diseases, including heart disease and certain cancers.[1] To achieve these objectives, public health professionals must find effective methods of integrating behavioral and psychosocial factors into nutrition-related behavior change programs. Because most behavior change interventions are designed for individuals who are already prepared for action, they may be inappropriate for those not yet ready to act.[2]

The Partners in Prevention–Nutrition program was designed to influence dietary intake by providing mailed, individually computer-tailored messages that address dietary and psychosocial factors and provide specific strategies for change. The intervention used a stage-of-change approach, based on the Prochaska and DiClemente transtheoretical framework,[3] to match tailored communications to the needs of participants at different points in the decision process for dietary change. We hypothesized that providing information relevant to an individual's stage of change would promote movement from earlier to more advanced stages of readiness, ultimately leading to actual behavior change. Accordingly, we conducted a randomized trial using a pretest and posttest to assess the impact of tailored vs nontailored nutrition education materials on fat, fruit, and vegetable consumption.

Methods

Study Population

Respondents were 558 adult patients (ages 18 and above) recruited from four family practices in central North Carolina between September and November 1991. Two practices served a primarily urban population and two were primarily rural. Family practice office staff recruited participants as they checked in for any type of medical appointment. Office staff excluded patients who were too ill or mentally unable to complete the baseline survey. Only one family member per household was allowed to participate.

The study sample was selected from an initial pool of 682 individuals who met eligibility criteria. A total of 124 people (18.2%) were excluded during the baseline survey phase for the following reasons: refusals (8.8%), consent form not signed (3.7%), ineligible due to age (< 18) or multiple household membership (2.2%), survey incomplete (3.4%), and participation in a related study (one individual). An additional 95 participants (13.9%) were lost during the follow-up survey phase.

Procedures

Participants were assessed initially regarding fat, fruit, and vegetable dietary intake; gender; age; race; education; marital status; physician-prescribed diets; pregnancy status (women only); stage of readi-

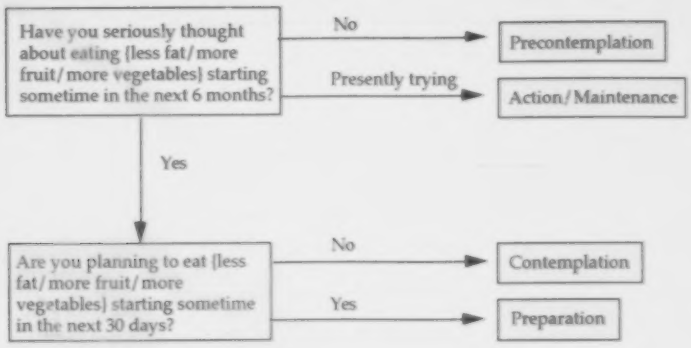

FIGURE 1—Stages of dietary behavior change.

ness to change diet; and psychosocial factors associated with dietary behavior change, such as self-efficacy (confidence in one's ability to change). The self-administered surveys were distributed and collected by family practice staff. Nearly all patients (99%) were able to complete the survey while in the family practice office; those who could not were allowed to take it home and return it using a postage-paid envelope. Participants were then randomly assigned to one of three groups: an intervention group, which received tailored nutrition messages; a comparison intervention group, which received nontailored nutrition messages; and a control group, which did not receive nutrition messages. All messages were mailed to participants within 3 weeks of baseline survey completion.

Participants were resurveyed 4 months postintervention to assess change. Household income also was assessed at follow-up. Through the use of a combined mail and telephone strategy, a final response rate of 82.3% (n = 459) of baseline participants was achieved. Telephone interviewers were blinded to participants' study group membership. Reasons for nonresponse included refusals (3.2%), passive refusals[4] (7.9%), no answer after 15 attempts (0.2%), and disconnected phone or no telephone number provided (5.7%). Four individuals (0.7%) were not resurveyed because one had moved with no forwarding address and three were found to be members of households that included another study participant. Respondents to the follow-up survey were more likely to be married than were nonrespondents; no other demographic or dietary differences distinguished respondents from nonrespondents.

Measures

Food frequency. A food frequency instrument consisting of 28 items derived from the Health Habits and History Questionnaire[5] was developed for this study. Items assessing fat intake included 13 items validated as a brief fat screener[6] plus 5 items representing high-fat foods commonly consumed by southern US populations. Ten items were used to assess fruit and vegetable consumption. Response options were presented as a checklist, with seven response choices: three or more times per day, two per day, about every day, two to four per week, once a week, one to three times per month, and rarely or never. Dietary fat and saturated fat scores were obtained by multiplying frequency of consumption (calculated as servings per day) by portion data for each item[5,7] and summing the items. Fruit and vegetable combined intake was obtained by calculating the frequency of consumption of each item and summing the frequencies to determine total daily servings.

Stage of change. Stage of readiness to change diet was measured for three consumption behaviors: decreasing fat, increasing vegetables, and increasing fruit. Based on a series of questions derived from the Prochaska and DiClemente stages of change for smoking cessation[8] (Figure 1), participants were categorized at baseline as being in one of the following stages: precontemplation (not seriously thinking about change), contemplation (seriously thinking about change within the next 6 months), preparation (planning to change within the next 30 days), or action/maintenance (currently trying to change). The stages-of-change model defines maintenance as continuing behavior change for longer than 6 months, whereas action includes behavior change efforts of less than 6 months.[8] Action and maintenance stages were combined here because our study design did not allow for long enough follow-up to assess maintenance of change. Because 91% of contemplators were planning to change within the next 30 days, the contemplation and preparation stages were also combined into one category (contemplation) for data analysis.

Psychosocial issues. Motives for change and barriers to change were assessed using questions derived from pretesting. Self-efficacy regarding ability to increase fruits and vegetables and to decrease dietary fat was measured using a 4-point scale (1 = very confident, 4 = not at all confident). For fat reduction, three subbehaviors were measured (lowering meat fat, dairy fat, and fats added to foods). Beliefs about perceived susceptibility to diet-related diseases and perceived benefit of dietary change to avoid health problems were also measured using a 4-point scale (1 = very likely, 4 = not at all likely). Participants contemplating change were questioned about past efforts to change and their continuation or relapse after those efforts. These psychosocial variables were measured for use in providing individualized computer-tailored feedback.

Intervention

The tailored intervention consisted of a one-time, mailed nutrition information packet tailored to the participant's stage of change, dietary intake, and psychosocial information. The health behavior literature indicates that tailoring can be an effective tool to address specific psychosocial issues and barriers to change.[9] Through the use of a tailored approach, individuals can be given behavior change information relevant to their stage in the decision process, whereas information not likely to be helpful at that stage can be omitted.

The tailored messages were created with Authorware Professional and Microsoft Word software for the Apple Macintosh computer. A library of text messages was developed to target each survey response choice regarding stage of change, motives, barriers, beliefs, and self-efficacy for each dietary behavior.[10] A team of nutritionists and health educators created, pretested, and revised the messages. Computer algorithms were developed to

access the appropriate text pieces based on each individual's baseline information. The computer then merged the text pieces into tailored nutrition education newsletters using a predetermined overall format.

Baseline food frequency information was used to provide individualized feedback about whether dietary change was needed. For dietary fat, participants were given feedback in graphic form depicting their current intake as "high" or "low-moderate." This evaluation was made by comparing the individual's dietary score with the 75th percentile of the distribution of fat intake in this population, as determined by pretesting with 55 family practice patients prior to the study. For fruits and vegetables, baseline information was used to show the number of daily servings the individual consumed compared with the recommended five or more servings per day.

Messages were structured according to a framework based on the stages of change and the Health Belief Model.[11] All tailored group members were mailed a packet containing a nutrition profile summarizing their current diet and level of interest in changing behavior, a tailored page regarding dietary fat intake, and a tailored page regarding fruit and vegetable intake. Each message acknowledged the participant's stage and addressed his or her beliefs about both susceptibility to diet-related diseases and perceived benefits of and motives for changing diet. Individualized diet feedback was then provided regarding baseline fat and fruit/vegetable intake. Contemplators received information designed to decrease barriers to change and to increase self-efficacy. Depending on stage of change, self-efficacy, and history of past relapse, participants also received tailored recipes and specific diet tips designed to promote skills and to provide cues to action. Those individuals who were already trying to change received tailored recipes and messages aimed at preventing relapse.

The nontailored messages appeared nearly identical to the tailored messages in format, typeface, and paper; however, no individualized dietary or psychosocial information was given. Instead, these messages provided standard risk information about the relation of diet to disease and gave dietary recommendations based on the 1990 *Dietary Guidelines for Americans*.[12] Control group members completed the baseline and follow-up surveys but did not receive any nutrition information from the Partners in Prevention–Nutrition program.

TABLE 1—Family Practice Patients' Baseline Dietary Intake, by Demographic Group and Stage of Change

		Fat (g/day)		Saturated Fat (g/day)		Vegetable/Fruit (servings/day)	
	No.	Mean (SE)	*P**	Mean (SE)	*P**	Mean (SE)	*P**

Marital status							
Married	348	49.4 (2.5)	.074	20.1 (1.2)	.072	3.3 (.20)	.117
Nonmarried	204	45.6 (2.6)		18.4 (1.1)		2.9 (.20)	
Stage[a]							
Precontemplation	141	47.5 (2.4)	<.05	19.3 (.96)	<.01	3.1 (.19) (n = 156)	<.005
Contemplation	253	44.7 (1.8)		17.8 (.71)		3.1 (.15) (n = 217)	
Action	164	40.0 (2.0)		15.7 (.79)		3.9 (.24) (n = 185)	

[a]As shown, numbers of participants in each stage of change differed for reducing fat versus increasing fruits and vegetables. The table shows vegetable/fruit-combined consumption according to stage of change for increasing vegetables. The same variables were significant when vegetables and fruit were analyzed separately by respective stage of change.
**P* values for dietary differences are based on *F* tests after adjustment for all effects in the model.

Analysis

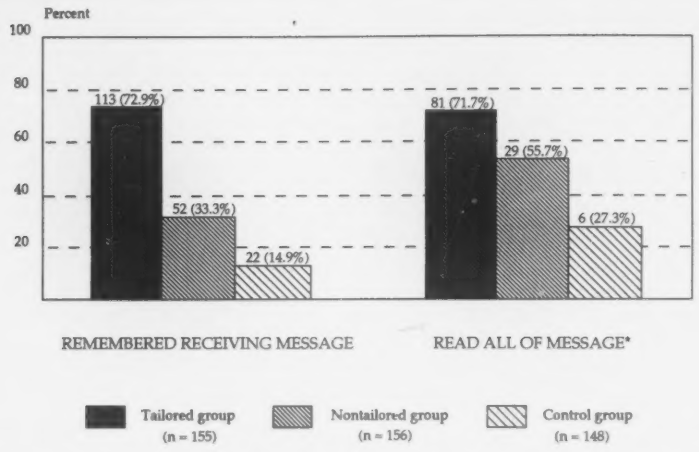
All dietary variables showed a skewed distribution and were transformed to conform more closely with a normal distribution. For fat data, least squares adjusted means were calculated after transformation by the natural logarithm ($e^{\bar{z}}$, where $\bar{z}$ = ln fat or ln saturated fat); standard error was approximated by SE = $(e^{\bar{z}})SE(\bar{z})$. For fruit and vegetable data, least squares adjusted means were calculated from square root transformed variables ($\bar{z}^2$, where $\bar{z}$, = square root daily servings); standard error was approximated by SE = $(\bar{z})^2SE(\bar{z})$. Analysis of covariance was used to test between-group differences for continuous variables, and logistic regression analysis was used to test differences among categorical variables.

Results

Descriptive Results

The study sample was primarily female (75.3%), married (62.3%), and well educated (mean = 13.6 years), with an average age of 40.8 years (Table 1). Minority enrollment was 19.0% of the sample, nearly all African Americans. Of 401 participants who reported their income (87.4% of the follow-up sample), the median annual household level was $30 000 to $39 000. There were no significant differences in demographic, dietary, or stage-of-change variables among study groups. The tailored intervention group consumed more dietary fat at baseline compared with the other two groups; this difference was not statistically significant.

We examined the relationship between stage of dietary change and baseline dietary intake scores, controlling for demographic variables (see Table 1). Self-reported stage of change was a significant predictor of baseline intake. Precontemplators and younger participants consumed significantly more total fat and saturated fat, and fewer fruits and vegetables, than did individuals in the action stage and older participants. Similarly, men and participants with up to 12 years of education consumed more fat and



Note. There are differences in remembering having received the message between the three study groups, $P < .0001$. There are also differences in message readership between the tailored and nontailored study groups, $P < .05$.

FIGURE 2—Differences between study groups in message recall and amount read.

TABLE 2—Comparison of Tailored Message, Nontailored Message, and Control Groups' Reported Consumption of Fat, Saturated Fat, and Fruits/Vegetables at 4 Months Postintervention

Baseline	41.1 (2.1)	...	16.3 (.98)	...	3.6 (.20)	...
Follow-up	39.8 (1.9)		15.8 (.81)		3.3 (.20)	
Difference[b]	−1.3		−0.5		−0.3	

Note. Group means are adjusted for baseline intake and the demographic variables of gender, age, education, race, marital status, and income. After deletion of individuals with missing demographic information, n = 394 in the final sample.

[a]*P* values for dietary differences are based on *t* tests after analyses of covariance, comparing each intervention group with the control group.

[b]Difference is computed by subtracting follow-up adjusted mean from baseline adjusted mean. Minus signs are shown to indicate the direction of change.

fewer fruits and vegetables than did women and participants with higher education.

Intervention Effects

As shown in Figure 2, study group (tailored message, nontailored message, or control) was a significant predictor of remembering having received a message ($\chi^2 = 116.35, P < .0001$). A total of 72.9% of individuals in the tailored group recalled receiving nutrition information, compared with 33.3% of the nontailored group and 14.9% of the control group (to whom no message was sent). Study group also predicted message readership among those who remembered having received a message. Members of the tailored group were more likely to report having read all the message than were those in the nontailored group ($\chi^2 = 3.98, P < .05$).

We used analysis of covariance to test the effect of study group on decrease in total fat and saturated fat intake scores while controlling for baseline intake and demographic variables (see Table 2). An overall test of study group effect was marginally significant ($F = 2.37, P < .10$), indicating that differences existed among groups. We then performed contrasts using *t* tests to examine between-group differences. For both total fat and saturated fat, the difference was statistically significant for the tailored group–control group comparison ($t = -2.14, P < .05$ for total fat; $t = -2.11, P < .05$ for saturated fat) but not for the nontailored group–control group comparison. Total fat decreased by 23% (10.3 g) in the tailored group, compared with a decrease of 9% (3.6 g) in the nontailored group and 3% (1.3 g) in the control group. The tailored group decreased saturated fat by 26%, compared with decreases of 11% in the nontailored group and 3% in the control group.

Analysis of covariance was also used to examine study group effect on increase in fruit and vegetable consumption while controlling for baseline intake and demographic variables (Table 2). Study group did not predict an increase in fruit and vegetable intake; consumption decreased by approximately one quarter of a daily serving in all groups.

Discussion

This randomized trial demonstrated a positive effect of tailored nutrition messages in promoting dietary change efforts for disease prevention. Participants who were sent tailored messages were more than twice as likely as those who were sent nontailored messages to remember receiving the information. Those who remembered receiving a message were more likely to report having read all of it if the message was tailored than if it was not tailored. At posttest, participants in the tailored intervention group had reduced their total fat and saturated fat intakes significantly compared with participants in the control group. Members of the nontailored group had reduced intake also; however, the level of change was not significant when compared with that of the control group.

Use of dietary change as an outcome measure assumes that diet modification

will reduce disease risk in the future. The *Healthy People 2000* objectives[1] recommend lowering dietary fat intake to 30% or less of total calories, compared with the current 36% to 38% of calories consumed by most Americans. This corresponds to a recommended reduction in fat intake of about 17% to 21%. In the present study, the tailored message group reduced their fat score by approximately 23% from baseline intake, suggesting that they achieved a level of change commensurate with the *Healthy People 2000* objectives. It is possible, however, that by using a brief assessment instrument, significant sources of dietary fat were missed, and this could have biased the results. The food frequency instrument was designed for self-administration by patients waiting for their physician appointment, and it included only 18 items to measure dietary fat. This instrument did not collect enough information to determine the percentage of calories consumed as fat, which would have provided a more valid and reliable estimate of dietary change. Attempts were made to reduce possible bias by using a randomized design and controlling for baseline intake in the analysis.

The descriptive findings show that the stage-of-change framework can be applied to dietary behaviors in that self-reported stage information was associated with baseline dietary intake. Precontemplators consumed the most fat and the fewest fruits and vegetables at baseline, whereas individuals in the action stage consumed the least dietary fat and the most fruits and vegetables. These results are consistent with other research demonstrating the relation of stage of change to percentage of calories consumed as fat.[13] Our findings suggest that the stages of change are also related to fruit and vegetable dietary behavior.

The observed lack of an intervention effect on fruit and vegetable consumption may have been partly due to seasonal factors. Baseline surveys were completed in the fall, and follow-up surveys were completed in the early spring with respondents being asked to recall the preceding 3 (winter) months. Seasonal variation in fruit and vegetable intake has been documented in other studies.[14] A number of participants commented during the telephone interviews that they planned to increase their intake of fruits and vegetables but were waiting until those foods came into season.

A potential bias in this study is the possibility of higher demand characteristics of the tailored messages, compared with the nontailored information. The tailored messages were personalized and provided more information than did the nontailored messages; therefore, tailored group members may have felt a stronger obligation to report positive changes at follow-up. We attempted to minimize the impact of demand characteristics, however, by designing both intervention materials similarly in terms of layout, logo, type, and paper; by sending personalized cover letters from the family physicians with all follow-up surveys; and by blinding telephone interviewers to study group membership.

The study findings have implications for public health and primary care practice. Individualized health and nutrition guidance has traditionally been provided by physicians, nurses, or nutritionists in the form of individual patient counseling, which is costly, time-consuming, and usually offered only to patients at high risk of diet-related morbidity. Standard practice is to provide nontailored written materials to patients. The present study shows that family practice patients are willing to participate in nutrition education programs designed to prevent chronic diseases, and that computer technology can be used to provide individually tailored information that is more effective than standard educational materials in promoting behavior change. Because computer-tailored education is relatively inexpensive compared with individual counseling, it can be provided to low-risk as well as to high-risk individuals who are interested in improving their health.

This study was conducted in a family practice population. Individuals who obtain care from family physicians may differ from the general public in sociodemographic characteristics and in motivation to participate in health promotion activities. The study sample was of higher education and income status than average for North Carolina. Prior research suggests that tailored mammography screening messages are more effective than nontailored messages for lower-income and minority women.[15] Future research should evaluate the impact of tailored messages in low-literacy populations. □

The Use of Vitamin Supplements and the Risk of Cataract among US Male Physicians

Johanna M. Seddon, MD, William G. Christen, DSc, JoAnn E. Manson, MD, Fran S. LaMotte, BS, Robert J. Glynn, DSc, Julie E. Buring, DSc, and Charles H. Hennekens, MD

ABSTRACT

Objectives. The purpose of this study was to examine prospectively the association between reported use of vitamin supplements and risk of cataract and cataract extraction.

Methods. The study population consisted of 17 744 participants in the Physicians' Health Study, a randomized trial of aspirin therapy and beta-carotene among US male physicians 40 to 84 years of age in 1982 who did not report cataract at baseline and provided complete information about vitamin supplementation and other risk factors for cataract. Self-reports of cataract and cataract extraction were confirmed by medical record review.

Results. During 60 months of follow-up, there were 370 incident cataracts and 109 cataract extractions. In comparison with physicians who did not use any supplements, those who took only multivitamins had a relative risk of cataract of 0.73 after adjustment for other risk factors. For cataract extraction, the corresponding relative risk was 0.79. Use of vitamin C and/or E supplements alone was not associated with a reduced risk of cataract, but the size of this subgroup was small.

Conclusions. These data suggest that men who took multivitamin supplements tended to experience a decreased risk of cataract and support the need for rigorous testing of this hypothesis in large-scale randomized trials in men and women. (*Am J Public Health.* 1994;84:788–792)

Introduction

Cataract is the leading cause of blindness and visual impairment in the world.[1] In the growing US elderly population, cataract is a leading cause of functional impairment and morbidity,[2] and cataract surgery has become the most common procedure performed among people more than 65 years of age.[2] Modifiable preventive factors such as diet (including vitamin supplementation) are receiving increased attention and merit careful evaluation.

Nutritional factors, particularly vitamins with antioxidant properties, may affect cataract development, possibly by protecting against free radical oxidative damage that results from many normal metabolic processes as well as exposure to ultraviolet light.[3,4] At present, data concerning the possible associations between vitamins and cataract are sparse and inconsistent.[5–14] We therefore sought to determine whether vitamin supplementation affected risk of cataract in a large prospective cohort of male physicians participating in the Physicians' Health Study.[15]

Methods

Study Population

The subjects and methods of the Physicians' Health Study have been described previously.[15] Briefly, the study is a randomized, double-masked, placebo-controlled trial that has tested (in a 2 × 2 factorial design) the effect of low-dose aspirin therapy (325 mg every other day) on the risks of cardiovascular disease and is continuing to evaluate beta-carotene (50 mg on alternate days) in the prevention of cancer and cardiovascular disease. The study involves 22 071 US male physicians who were 40 to 84 years of age in 1982. On January 25, 1988, the randomized aspirin component of the study was terminated early, principally as a result of the emergence of a statistically extreme 44% reduction in risk of a first myocardial infarction among those assigned to aspirin.

Supplement and Risk Factor Data

At baseline, participants completed questionnaires that requested information about dietary supplements. Questions included whether multiple vitamins had been taken regularly (never, past only, or current) and the number of years taken (if current). Questions were also asked about whether participants had ever regularly taken capsules containing only vitamin A, only vitamin C, and only vitamin E (never, past only, or current). For each vitamin currently used, partici-

pants reported the number of years taken. In these analyses, subjects who reported current use of supplements were classified as supplement users. Since beta-carotene was an assigned treatment, those who reported vitamin A use were ineligible for enrollment in the Physicians' Health Study and were excluded. Although a complete dietary questionnaire was not administered, information was provided on a number of baseline characteristics, including cigarette smoking, alcohol use, history of diabetes mellitus, history of hypertension, history of high cholesterol, height, weight, physical activity, and parental history of myocardial infarction. This report includes 17 744 participants who provided complete information about vitamin supplements and other risk factors and reported that they did not have cataract at baseline.

Cataract Diagnoses

Follow-up questionnaires were sent at 6-month intervals during the first year and annually thereafter; these questionnaires requested information about compliance and occurrence of incident diseases, including cataracts. After report of a cataract diagnosis or extraction, a written consent requesting the name and address of the treating ophthalmologist was obtained. Ophthalmologists were contacted by mail and completed a cataract questionnaire that asked about the presence of lens opacities, visual acuity loss, cataract extraction, other ocular abnormalities that could explain visual acuity loss, cataract type, and primary cause (including age related, traumatic, congenital, inflammatory, or surgery or steroid induced). Alternatively, the ophthalmologists could supply photocopies of the relevant medical records.

The endpoints for this analysis were incident cataract and cataract extraction. Cataract was defined as follows: self-report, confirmed by medical record review, initially diagnosed after randomization, age related in origin, with best corrected visual acuity of 20/30 or worse and no alternate ocular pathology to explain the visual acuity loss. In the presence of alternate ocular pathology, a lens opacity was considered a cataract if, in the judgment of the ophthalmologist, the opacity was of sufficient severity to reduce visual acuity to 20/30 or worse when considered alone. Extraction was defined as the surgical removal of an incident cataract. For the present report, we followed the 17 744 eligible participants from randomization until January 25, 1988, the date the randomized aspirin component of the trial was terminated. The average length of follow-up was 60.2 months.

Data Analysis

Incidence rates of cataract and cataract extraction were obtained by dividing the number of incident cases by person-years of follow-up in each category of supplement use. Categories of vitamin use were vitamin C and/or E only, multivitamins only, multivitamins plus vitamin C and/or E, and no supplement intake. Relative risks (RRs) were computed as the rate of cataract in a specific category of supplement use divided by the corresponding rate among nonusers.

Data were analyzed separately for cataract diagnoses and extractions. Crude relative risk estimates controlled for age as well as randomized aspirin and beta-carotene assignment. In proportional hazard models used to control for multiple potential confounders, indicator terms were added for smoking (never, past, current), history of diabetes, history of hypertension (systolic blood pressure of 160 mm Hg or greater, diastolic blood pressure of 95 mm Hg or greater, or history of treatment for high blood pressure), history of high cholesterol (reported history of treatment for high cholesterol or reported blood cholesterol of 260 mg/dL or greater), obesity (body mass index of 27.8 kg/m^2 or greater), alcohol use (reported daily or weekly use), physical activity (reported vigorous exercise once per week or more), and parental history of myocardial infarction. Stratified analyses were performed to evaluate any possible modification of the effect of vitamin supplement use on cataract by category of smoking (never, past, current). Those not using supplements were the referent within each category of smoking.

For each relative risk, two-sided P values and 95% confidence intervals (CIs) were calculated.[16] Individuals, rather than eyes, were the unit of analysis because eyes were not examined independently and participants were classified according to the status of the worse eye. When the worse eye was excluded because of loss of visual acuity attributed to other ocular abnormalities or a cause that was not age related, the other eye was used for classification.

Results

There were 370 incident cataracts and 109 cataract extractions during follow-up. At baseline, 12.5% of the participants reported multivitamin use only, 7.5% used multivitamin supplements plus C and/or E, and 4.1% reported vitamin C and/or E supplementation. The distribution of baseline characteristics that are possible risk factors for cataract are presented according to supplement status in Table 1. Vitamin supplement users tended to be older and reported more physical activity, more hypertension, and less obesity.

As seen in Table 2, in analyses adjusted for age and randomized treatment assignment, multivitamin-only users had a marginally significant decreased risk of incident cataract relative to nonsupplementers (RR = 0.75, 95% CI = 0.55, 1.01). After adjustment for other potential cataract risk factors, the relative risk was 0.73 (95% CI = 0.54, 0.99). Users of vitamin C and/or E alone, however, did not appear to have a reduced risk of cataract, but the numbers were small. Multivitamin users who also used supplements containing only vitamin C and/or E had a risk of incident cataract similar to users of multivitamins only. The relative risk of cataract decreased with increasing duration of any use of multivitamins, an apparent trend of borderline statistical significance (P = .06) (Table 3).

The adjusted relative risk for cataract extraction among multivitamin users only (0.79, 95% CI = 0.46, 1.35) was similar to that for cataract diagnosis. Risk of cataract extraction was not reduced among participants taking vitamin C and/or E alone. However, as with cataract diagnosis, the number of cataract extractions in this subgroup was small.

The association between any multivitamin use and risk of cataract within categories of cigarette smoking was also assessed. Among those who never smoked, the relative risk was 1.10 (95% CI = 0.76, 1.60) after adjustment for other risk factors. However, among past and current smokers, the risk of cataract was reduced among multivitamin users relative to nonusers (RR = 0.61, 95% CI = 0.42, 0.90, and RR = 0.38, 95% CI = 0.16, 0.92, respectively). This trend for a reduction in risk among multivitamin users who smoked was statistically significant (P = .008). Numbers were too small to evaluate smoking among users of vitamins C and/or E only or the endpoint cataract extraction.

TABLE 1—Differences in Sample's Baseline Characteristics That Are Known or Potential Risk Factors for Cataract, by Supplement Status

	Vitamin C and/or E Only	Multivitamin Only	Multivitamin and C and/or E	No Vitamins
Total n	729	2222	1331	13 462

[a]Adjusted for age and randomized treatment assignment.
[b]Adjusted for age, randomized treatment assignment, history of diabetes mellitus, history of hypertension (systolic blood pressure of 160 mm Hg or greater, diastolic blood pressure of 95 mm Hg or greater, or history of treatment of high blood pressure), obesity (body mass index of 27.8 kg/m² or greater), alcohol (reported daily or weekly use), physical activity (reported vigorous exercise once per week or more), parental history of myocardial infarction, high cholesterol (reported treatment for high cholesterol or reported blood cholesterol of 260 mg/dL or greater), and smoking status (never, past, or current).

Discussion

These prospective data are compatible with the possibility that vitamin users may have a lower risk of cataract and cataract extraction. If real, even modest decreases in risk such as those suggested in this study are potentially important, given the high prevalence of cataract, the enormous costs associated with cataract extraction, and the feasibility of dietary changes or micronutrient supplementation.

The prospective design of this study precludes the possibility of bias in reporting supplementation use based on disease outcome, since vitamin supplement use was reported at baseline prior to questions regarding the cataract outcomes and only incident cataracts diagnosed after this baseline period were included in the analyses. Because of the mail questionnaire design, the diagnoses of cataract and cataract extraction were based on medical record confirmation. There were essentially no false-positive cases of cataract extraction and, because we required medical record documentation, probably very few if any false-positive incident cataracts. Although there may have been cases that were not ascertained (false negatives), such underascertainment should not bias the relative risks in a cohort study if not associated with exposure.[17,18] Differential misclassification of cataract based on supplement use was extremely unlikely, since medical records were reviewed without knowledge of the participants' exposure data and treating ophthalmologists would have been generally unaware of the participants' dietary habits or the vitamin–cataract hypothesis, which has only been reported recently.

It is possible that multivitamin supplement users may be more health conscious and may, therefore, have more (or less) medical contacts, which would increase (or decrease) the likelihood of having a cataract diagnosed. However, all participants in this study are physicians, so their overall level of medical care is likely to be reasonably uniform, with no large differences between users and nonusers of supplements. Misclassification of vitamin intake is unlikely, since use of supplements is usually accurately recalled.[19] Such misclassification, if present, would probably be random and would tend to bias associations toward the null. Incomplete follow-up is not an issue in this study. Morbidity follow-up was 99.3% complete as of January 25, 1988, and ocular medical records were obtained for more than 90% of both users and nonusers of supplements.

Several known or potential risk factors for cataract, such as diabetes and smoking status, were controlled in the analyses. Of course, the effects of unmeasured or unknown factors cannot be controlled in an observational study. It is possible that users of multivitamins differed from nonusers in ways that were not measured and therefore, could not be adjusted for in these analyses. For example, we were unable to control accurately for the effects of sun exposure. It is unlikely that there are large differences in

sun exposure, however, among this homogeneous group of male physicians, with most having no occupational exposure to sunlight. This possibility is supported by the lack of an association between geographic region and cataract when this variable was included in the multivariate models.

Foods rich in vitamins with antioxidant properties are now considered to have the potential to prevent many chronic diseases, including coronary heart disease and cancer.[20] A similar role has been hypothesized in the formation and progression of cataract[21] that centers on the protective action of certain micronutrients against free radical oxidative damage.[22,23] Experimental studies have demonstrated that both vitamin C[22] and vitamin E[23] prevent lipid peroxidation in response to photo-oxidative assault and limit lens damage after oxidative insult in animals fed these vitamins.[24,25] A few epidemiologic studies have also evaluated the association between antioxidant nutrient status and cataract.[5–14] Some of these cross-sectional or retrospective studies have found an inverse association between cataract and plasma[5] or dietary[7,8] vitamin C, plasma[14] or dietary[7,8] vitamin E, and use of multivitamins.[8] In contrast, others have not shown an inverse association with vitamins C, E, or beta-carotene[9,10,14] or with use of multivitamins.[7] Data from two studies that used prospectively identified cases have also been conflicting. Inverse associations with cataract or cataract extraction were reported for dietary carotenoids,[12] long-term vitamin C supplementation,[12] and plasma levels of vitamin E and beta-carotene.[13] On the other hand, no associations were observed between the cataract endpoint and dietary vitamins C or E.[12]

Our prospective data, combined with evidence from previous studies, are compatible with the possibility that multivitamin supplements are related to cataract. Although the numbers are small, our findings regarding separate supplementation with vitamins C and E, which both have antioxidant properties, do not suggest a protective effect for these vitamins used either alone or in addition to multivitamins. The antioxidant properties of multivitamins, which contain vitamins C and E, represent a plausible mechanism by which risk of cataract may be reduced. However, there may be other components of multivitamins separate from antioxidants that offer protection. Further laboratory and clinical research is needed to elucidate mechanisms to understand how multivitamin supplementation may affect risk of cataract.

TABLE 3—Association between Duration of Multivitamin Supplement Use and Risk of Cataract

	Duration of Use, y[a]			
	<5	5–10	>10	*P* for Trend
No. of cataracts	32	11	18	...

Full model[c]				
Relative risk	0.88	0.74	0.68	.06
95% confidence interval	0.61, 1.27	0.40, 1.35	0.42, 1.10	...

[a] n = 3553 (2222 multivitamin users and 1331 multivitamin plus C and/or E users).
[b] Adjusted for age and randomized treatment assignment.
[c] Adjusted for age, randomized treatment assignment, history of diabetes mellitus, history of hypertension (systolic blood pressure of 160 mm Hg or greater, diastolic blood pressure of 95 mm Hg or greater, or history of treatment of high blood pressure), obesity (body mass index of 27.8 kg/m^2 or greater), alcohol (reported daily or weekly use), physical activity (reported vigorous exercise once per week or more), parental history of myocardial infarction, high cholesterol (reported high cholesterol or reported blood cholesterol of 260 mg/dL or greater), and smoking status (never, past, or current).

Results of our analyses also raise the possibility of a benefit of multivitamin supplementation on risk of cataract, primarily among the subgroups of past and current smokers. Although it is plausible that supplementation might help particularly those with reduced levels of nutrients related to oxidative stress, as may occur among smokers, our subgroup findings are speculative, based on small numbers, and require further study.

As is the case with detection of small to moderate benefits, observational studies have amounts of uncontrolled or uncontrollable confounding that may be as large as the effects being postulated. Thus, the only reliable means to determine whether antioxidant vitamins decrease cataract is through large-scale randomized trials.[17,26] In this regard, the National Eye Institute's Age-Related Eye Disease Study[26] is testing vitamins C, E, and beta-carotene, as well as zinc; the Physicians' Health Study[27] is evaluating beta-carotene; and the Women's Health Study[28] is testing beta-carotene and vitamin E. All of these data will provide relevant and complementary information to a body of evidence on which reliable clinical decision making and public policy can safely be based.

In summary, these prospective data from the Physicians' Health Study suggest that multivitamin supplementation may be associated with a modest decrease in the risk of cataract. Results were marginally significant and were derived from an observational study design. Findings support the need for large-scale randomized trials in men and women to evaluate definitively the possibility that micronutrient supplementation may reduce the worldwide burden of blindness due to cataract. □

High Temporal, Geographic, and Income Variation in Body Mass Index among Adults in Brazil

Rosely Sichieri, MD, PhD, Denise C. Coitinho, MPH, Marília M. Leão, Elisabetta Recine, MPH, and James E. Everhart, MD, MPH

ABSTRACT

Objectives. Population-based data on body mass index for developing countries are scarce. Body mass index data from two Brazilian surveys were examined to determine regional and temporal variations in the prevalences of underweight, overweight, and obesity.

Methods. Nationwide surveys in 1974/75 and 1989 collected anthropometric data in Brazil from 55 000 and 14 455 households, respectively. Trained interviewers used the same methods to measure weight and stature in both surveys, and survey designs were identical. Prevalences of underweight, overweight, and obesity were determined for persons 18 years of age and older.

Results. In the 1989 survey, body mass index varied greatly according to region of the country, urbanization, and income. In the wealthier South, the prevalence of overweight/obesity was the highest and the prevalence of underweight was the lowest; in the poorer rural Northeast, these patterns were reversed. For both surveys, overweight/obesity was more common among women than among men and peaked at age 45 to 64 years in both sexes. Over the 15 years between surveys, the prevalence of both overweight and obesity increased strikingly.

Conclusions. In contrast to findings in developed countries, obesity in Brazil was positively associated with income and was much more prevalent among women than among men. For Brazilian women, the overall prevalence of overweight was nearly as high as that among women in the United States. (*Am J Public Health.* 1994;84:793–798)

Introduction

Obesity is recognized as a condition characteristic of high-income societies.[1–3] Little is known, however, about the pattern of weight change within populations of developing countries. Increased mortality rates owing to obesity-related chronic diseases indicate that obesity may be an important risk factor in these countries,[4,5] but population-based data are scarce. In 1974/75 and 1989, the Brazilian Institute of Geography and Statistics conducted national representative surveys that measured the weight and stature of the participants. The purpose of this report is to describe demographic variations in the prevalence of underweight, overweight, and obesity based on body mass index and to compare the increased prevalence of overweight and obesity over the 15 years between surveys with such prevalences in developed countries.

Population and Methods

Study Population

Stature and weight have been measured in two nationwide nutritional surveys in Brazil: the Estudo Nacional da Despesa Familiar,[6] conducted in 1974/75, and the Pesquisa Nacional de Saúde e Nutrição,[7] conducted in 1989. The first was based on a national probability sample of 55 000 Brazilian households; the second was based on a representative population sample of 14 455 households. For both surveys, samples were selected from the urban and rural districts of the five major geographical regions of the country; the only area not included was the sparsely populated rural North. For both surveys, participants' households were selected using two-stage probability sampling. In the first stage, primary sampling units were selected from the nine major urban/rural regions of the country. In the second stage, households were sampled from the primary sampling units. Probability of selection of primary sampling units and households was proportional to the population in the nine areas. Household nonresponse for the 1989 survey was 10.8%, of which 99% was owing to failure to locate household occupants for interview and examination.

Measurement of the Variables

Stature and weight were collected in the households by two trained interviewers, with the interviewee wearing light clothes and no shoes. The scales were calibrated at each household, and for each person the measurements were taken twice. Scales were precise to 100 g. Height was measured using a platform with an attached measuring bar, precision was within 0.1 cm.

Per capita income was calculated as the preceding month's family income divided by the number of persons living on
